Incidence of TB is defined as the number of new cases arising in a given period of time (usually one year) in a given community, expressed as a rate per unit population, usually 100,000. Ideally, the incidence should include new, as well as relapse[¥] cases. Estimating the trends in rates of incidence is the most important epidemiological indicator to measure the progress towards disease control and elimination, since it reflects the number of people afflicted with the disease.

The commonly used approaches to estimate incidence are as under:

Cohort Studies

Meticulously carried out prospective cohort studies facilitate the direct measurement of incidence of PTB. Such studies involve repeat prevalence surveys within a reasonable period of time. New cases detected at the later

---

[Ω] *Sensitivity is the ability of test to detect disease among those who actually have the disease.*

[©] *Bacteriologically positive case of PTB: A person whose sputum is found to be positive for acid-fast bacilli, either on microscopy or culture, irrespective of the report of X-ray chest.*

[μ] *Abacillary case of PTB: A person whose sputum is found to be negative for acid-fast bacilli on microscopy, as well as on culture, but X-ray is suggestive of PTB.*

[¥] *A relapse case is the one who was declared cured on previous treatment for TB and gets a new episode of TB disease, which could be either a true relapse of the earlier episode or it could be an entirely new episode due to re-infection.*

Strengths	*Limitations*
Provide a direct measure of incidence.	Methodologically cumbersome. Costlier than surveys to estimate prevalence, because of the requirement of a larger sample size and the need to undertake repeat surveys. Need for intensive follow-up of the study population to diagnose all incidence cases that occur in between the follow-up examinations, some of these cases may be diagnosed outside the specific geographical area.

survey among persons not found to be suffering from TB disease at the time of the previous survey represent the incidence cases arising during the intervening period. Nevertheless, many new cases occurring in the intervening period may be missed by the virtue of cure or death. Therefore, information should also be obtained from the records of health centers in the area on additional new cases registered for anti-TB treatment during the period intervening between the two surveys.

Indirect Measurement from the Prevalence

Incidence can be estimated by dividing prevalence with the duration. For the purpose of estimating duration of bacteriological cases, the average delay in initiating treatment after the onset of pulmonary symptoms and the average duration of infectiousness after initiating treatment are considered. Delay on the part of the patient in seeking health care may be estimated through behavioral studies, which may be carried out along with prevalence surveys. However, care should be taken in estimating patient delay because patients usually under estimate the duration of their illness. The delay on the part of the health services in initiating treatment may be estimated through specially commissioned studies to find out the practices of health providers.

It has been estimated that the mean duration for which a bacteriological case remains culture positive after initiating treatment is three months. The disease durations are estimated separately for cases treated under DOTS, non-DOTS and those who remain untreated, by HIV status and then pooled to find out the mean duration.

Indirect Estimation from the Annual Risk of Tuberculosis Infection (ARTI)

ARTI is defined as the probability of acquiring new infection with tubercle bacilli over a period of one year. It is computed from the prevalence of infection estimated through a cross-sectional tuberculin survey among young children. A parametric relationship was proposed by Styblo during early 1980s, according to which every one percent of ARTI among children corresponded to 50 smear-positive incidence cases per 100,000 population per year.[39] This was derived from observations of six studies. However, only two of these studies measured the incidence directly through prospective cohort studies. It was derived indirectly from the prevalence of smear-positive PTB in two studies and from mortality due to TB in the other two studies.

In many countries, including in India, the incidence of smear-positive PTB has been estimated by applying Styblo's hypothesis. There is ample evidence that shows that this proposition may no longer be valid.[40] In a well performing DOTS program, the mean duration of infectiousness of the cases would be reduced and thus a larger number of incidence cases would be needed to infect one percent of the population. Similarly, in situations where significant proportions of TB cases are also infected with Human Immunodeficiency Virus (HIV), a shorter survival reduces the average duration of infectiousness for *M. tuberculosis.*[41,42] Therefore, in the present epidemiological environment, each one percent of ARTI should correspond to larger number of incidence cases.

Estimating Incidence from TB Notification Data

As conveyed above, estimating incidence from community-based surveys has its limitations. Presence of an efficient routine surveillance system, which fulfills the following minimum criteria offers an alternative for deriving incidence rates from case notification data.

- TB control activities well integrated with the general health system
- Universal access to TB diagnostic and treatment facilities, so that there is minimum diagnostic and treatment delay
- Quality assured laboratory procedures with adequate and timely supply of lab reagents
- Adequate and timely supply of anti-TB drugs
- Operational mechanism to trace initial defaulters
- Effective staffing in terms of vacancies, training and retaining the trained staff

- Correct classification of new and retreatment cases
- Efficient collaborative activities between HIV and TB control programs
- Effective coverage of health providers, including the private sector and NGOs, with respect to quality of the diagnosis, treatment and recording and reporting
- Efficient data management practices.

Since the implementation of DOTS, standardized case definitions and routine surveillance procedures under NTPs are now in place in most countries. In situations, where almost entire population have access to health services and most of the incidence TB cases are detected and reported to NTPs, the annual case notification rates could be equated with incidence rates. In such a scene, the trends in annual case notification rates reflect the trends in incidence provided that the efficiency of case finding does not vary with time. However, the surveillance data should be examined for completeness in the terms of reporting units, duplications and misclassifications, if any and whether the data are consistent with known epidemiology of the disease, i.e. the proportion of smear-positive cases out of all cases, proportion of pediatric cases, etc.

In majority of the developing countries, only cases having access to health services are included in the notification data of NTPs. In such situations, the notification data does not directly provide a fair assessment of the incidence rates. Also, there has been an intensification of case finding efforts in the recent years with the result that the present trends of increase in case notification rates cannot be equated to the trends in the incidence.

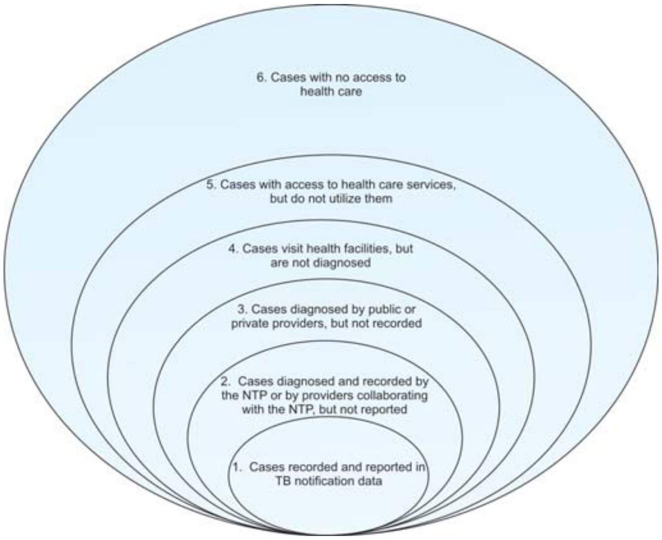
The following approaches may be used for deriving more reliable estimates of incidence, using the case notification data.

a. *Estimating missing cases:* Many cases are usually missed from notification under routine surveillance, due to various reasons:

i. A proportion of cases may not have any access to health care.

ii. A proportion may not seek care despite having access to health services, due to various reasons, such as non-perception of symptoms or the felt-need to seek care, home remedies or belief in traditional medicines.

iii. Some cases remain undiagnosed inspite of contact with health providers, due to failure on the part of the providers to diagnose TB owing to various reasons like technical skills and shortage of resources like laboratory reagents, etc.



6. Cases with no access to health care
5. Cases with access to health care services, but do not utilize them
4. Cases visit health facilities, but are not diagnosed
3. Cases diagnosed by public or private providers, but not recorded
2. Cases diagnosed and recorded by the NTP or by providers collaborating with the NTP, but not reported
1. Cases recorded and reported in TB notification data

Fig. 36.2: A schematic presentation of TB cases missed in notification data[43]

Note: The areas of the respective rings are arbitrary and do not imply the proportions of cases missed in each ring.

iv. Some cases may be diagnosed (and treated), but may not be recorded in the TB registers, due to administrative errors on the part of health staff.

v. Some cases inspite of having been registered and recorded may not be notified in case finding reports due to administrative errors.

Therefore, only a proportion of the incidence cases are ultimately included in the surveillance data. If we estimate the proportion of cases missed at each of the stages as above, the incidence in the community can be estimated on dividing the number of cases notified by the total proportion of cases that are missed through an "*Onion Model*" approach (Fig. 36.2). The information on the proportion of cases missed in each of the rings 2-5 can be estimated by conducting special investigations and studies besides using the available information.

This exercise assists to formulate appropriate strategy to improve the efficiency of the routine surveillance system and thus reduce the proportion of cases missed. It should be undertaken in each tuberculosis unit responsible for implementing control services in a given area.

b. *Inventory method:* In this method, data is collected from all possible sources and the total numbers of TB cases recorded are counted after checking for duplications. However, cases undiagnosed or not recorded will be missed.

c. *Capture-recapture technique:* This technique was originally developed by zoologists to count wildlife population. Such studies can be used to derive a better estimate of the real numbers of TB cases by finding out the proportion of under or overestimation of the case notifications by two independent sources.[44,45]

This method is based on several assumptions, importantly that there are no births, deaths or migrations in the area, i.e. it is a closed population, and that case definitions are correctly applied by both the sources.

There can be a degree of overestimation, if cases captured by both sources are not recognized as being the same (negative dependence). On the other hand, a positive dependence between the two sources would lead to underestimation. Nevertheless, the number estimated by capture-recapture study is likely to be closer to the truth than the numbers reported by NTP alone. Such studies also provide opportunities to find out the efficiency of the surveillance system of NTP. It is desirable to include a minimum of three sources of data for such a study. More the number of sources of data used for such exercises, more accurate are the number of estimated new TB cases. Capture-recapture studies may be utilized to estimate the number of TB cases that are diagnosed, but not reported (Rings 2 and 3 of Fig. 36.2).

Deriving Trends in Incidence from Age Distribution of Notified Cases

The age distribution of incidence cases and TB deaths throws light on trends. For example, at present, a majority of cases in the indigenous European population occur in the elderly people who were probably infected in the remote past when TB transmission rates were relatively higher.[38,46] Similarly, trends in mean age of notified cases can provide a clue to the direction of the epidemic.

A worsening of TB situation accompanied by increase in the TB incidence, for example in high HIV prevalence areas, leads to increase in the transmission of infection. This is accompanied by an increase in the proportion of cases emerging among the younger age group leading to reduction in the mean age of notified TB cases.[47] Conversely, implementation of effective TB control activities leads to a higher proportion of cases belonging to the older age group since the majority of cases in older people are caused by the reactivation of infection acquired in the remote past. This is accompanied by an increase in the mean age of incidence cases.[48,49] This must be interpreted cautiously since there are other factors, which may influence the age distribution of cases—increase in life-expectancy of the general population, increase in accessibility to health care resulting in the higher proportion of elderly cases seeking anti-TB services, errors in population projection in different age groups.

Measuring TB Mortality

TB mortality rate is defined as the proportion of individuals in the community who die of TB in a given period of time (usually one year), an important indicator to measure progress towards MDGs [*Deaths among HIV positive TB cases are not counted as TB deaths, and are classified under HIV deaths as per International Classification of Diseases (ICD-10)*].

Of the total burden of TB measured in "Disability-Adjusted Life Years (DALYs§)" lost, more than 80% is accounted by premature deaths rather than illness per se.[50] As an effective treatment drastically reduces the risk of death, efficient case finding and treatment activities have a faster impact on TB mortality than on incidence.

Direct estimation of TB mortality rate through prospective cohort studies is operationally difficult. Further, routine TB surveillance systems in most high burden countries do not provide accurate information on TB mortality rates due to a combination of multiple reasons, viz. less than 100% case detection rate, non-ascertainment of the Cause of Death (COD) among cases who died during treatment, deaths occurring due to TB after completion of treatment period not captured by surveillance data. Thus, recording and reporting data at best throws light on case fatality rates during the period of treatment. In such situations, the commonly used practical approaches to measure TB mortality are as under:

Using Vital Registration Data

The most cost-effective approach would be to have an efficient system of vital registration in place wherein the underlying cause for every death occurring in the community is identified, coded as per ICD, and reported. As of now, only a third of the deaths occurring worldwide are reported by the vital registration systems.[51] Especially, in most high burden TB countries, vital registration system is plagued by the lack of universal population coverage, inaccuracy in assigning COD and poor reporting.[51] Concerted efforts are being

---

§DALYs is a unit for measuring disease burden in time and is expressed as the number of healthy years of life lost due to disability or premature death.

made by individual countries to improve the functioning of vital registration systems.

Verbal Autopsy Studies

Verbal autopsy (VA) method is now increasingly used to find out the COD.[52-54] In this method, the information on events of deaths having taken place in a community is obtained from various sources such as hospital data, religious places, crematoria and community-based volunteers. The workers trained in verbal autopsy methods visit the houses of the diseased and conduct interviews with the close relative of the deceased. Pre-structured set of questions are put to the family members of the diseased, for each death occurring in the past one year, using a standardized questionnaire. Information is obtained on symptoms, duration of disease, anatomical site and COD as known to family members. The information from available hospital and other records is also obtained. The interviewer is required to write a narrative of events starting from the onset of illness till death. Later, each filled-in questionnaire is scrutinized by a medical officer and COD is assigned. The COD is subsequently coded as per ICD, by trained coders.

Verbal autopsy studies are especially useful for assigning COD in countries where the well functioning death registration systems are not in place, the methods need further standardization to reduce the mis-classifications. Before undertaking these studies in a given area, validation studies to find out sensitivity and specificity of COD should be carried out.

Indirect Derivation from Incidence Rate

This can be obtained by applying the formula: Mortality rate = incidence rate × case fatality rate.

Different rates of case fatality are applied for cases treated by DOTS programs, non-DOTS programs and untreated cases, by HIV status and pooled to estimate the average mortality rate. The limitations of this method are:

i. Deaths occurring during treatment are not always caused by TB, but are always attributed to TB in the DOTS surveillance system.
ii. Fate of TB cases who default from treatment or are transferred out is usually not known.
iii. Some cases may die due to TB even after having completed treatment.[55]

Measuring ARTI

Incidence rate of new tuberculous infections depends upon the load of infectious TB cases in the community, efficiency of TB control programs and socio-environmental factors that determine the extent of interaction between TB cases and susceptible individuals. Ideally, the incidence of infection can be measured through prospective follow-up studies of noninfected people. But there are major impediments to this approach, due to the possibility of reversion of tuberculin sensitivity with time and of boosting, which results from recall of waned cell-mediated immunity due to repeated tuberculin testing. To circumvent this problem, epidemiologists first estimate the prevalence of infection in the community by carrying out cross-sectional tuberculin surveys. It is assumed that a person once infected remains infected for the rest of his/her life. Prevalence of infection thus represents the cumulative effect of the incidence rates of infections experienced by the study sample during each of the individual years since birth.

The annual risk of tuberculosis infection (termed so, to distinguish it from incidence of infection) is computed from estimated prevalence of infection, using an appropriate formula. ARTI represents the average of the risks of tuberculous infection experienced by a group of individuals during each of the individual years from their birth to the time of the survey. The trends in ARTI have been observed to run in parallel with trends in prevalence of TB.[35,56-60] Thus, ARTI is an important epidemiological indicator to monitor the progress towards MDGs.

Prevalence of infection is generally measured through tuberculin surveys generally carried out among children since the ARTI rates estimated among them reflect on relatively recent disease situation. On the other hand, surveys, if carried out among older individuals would represent the average of the risks of infection over a longer period in the past. Also, a higher prevalence of infection with Nontuberculous Mycobacteria (NTM) in older age groups may interfere with the interpretation of the survey data.[61]

In most countries, e.g. in India, the BCG vaccination coverage is high. Thus, the small proportion of children without BCG scar is not adequately representative of the target population. Even though a majority of children vaccinated at birth elicit low levels of tuberculin sensitivity, inclusion of vaccinated children in the 0-4 years age group may interfere with the interpretation of the survey results. On the other hand, in the 5-9 years age group, inclusion of BCG vaccinated children has not been found to significantly influence the survey results.[62] Therefore, children between 5 and 9 years of age, including those with and without BCG scar, comprise the most appropriate study population for tuberculin surveys. Younger children may be included in a particular country if there is past evidence of BCG vaccination not influencing significantly the estimates of ARTI.

School-based surveys are operationally more convenient than house-based surveys. However, house-based surveys may be preferred in communities with low (<80%) school attendance since children not attending schools may be at a different risk of tuberculous infection. Tuberculin surveys require meticulous designing, planning, implementation, quality control of data collection and careful interpretation.[63,64] To study the trends, repeat tuberculin surveys may be carried out with an optimum interval of 5-8 years.

First step in analyzing the tuberculin survey data is to decide on the criteria for estimating the prevalence of infection.[65] For this purpose, frequency distribution graph is generated with reaction size on X-axis and percentage of reactors on Y-axis. A classical graph of tuberculin survey data is bimodal showing two distinct modes and an easily identifiable anti-mode (Fig. 36.3). The reactions to the left of the anti-mode most probably represent cross reactions due to infection with NTM or BCG vaccination. The reactions to the right of the anti-mode most probably represent the subgroup of children who are infected with tubercle bacilli. In a situation, where the anti-mode is clearly discernible, prevalence of infection may be estimated as the proportion of children having reactions equal to or larger than the anti-mode.

The anti-mode is usually not clearly identifiable in areas with moderate-to-high prevalence of NTM infections or when BCG vaccinated children are included in the study sample. In these situations, the prevalence of infection is estimated using "mirror–image technique". In this technique, the proportions of reactions larger than the second mode is doubled and added to the frequency at the second mode. The rationale of this approach is that tuberculin reactions due to infection with tubercle bacilli are distributed more or less similarly in the both sides of mode, as seen in a normal frequency curve. The influence of BCG-induced tuberculin sensitivity on estimate of prevalence of infection is minimal if the estimation is done using mirror–image technique, since tuberculin sensitivity induced by BCG vaccination rarely elicits reactions larger than the second mode.

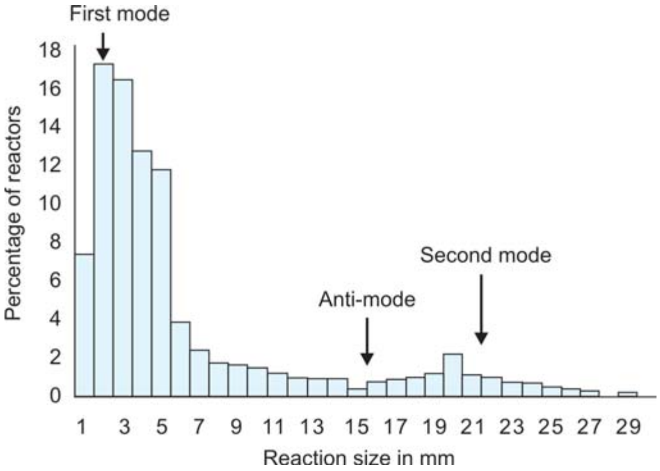


Fig. 36.3: An example of frequency distribution of tuberculin reaction sizes obtained in a survey

Sometimes, it is possible that neither the anti-mode nor the mode is clearly discernible on the frequency distribution graph. Such situations are quite likely in communities with the low prevalence of infection. In such a scenario, the mode observed in smear-positive cases may be used to select a cut-off point for estimating the prevalence of infection among children (distribution of reaction sizes among TB cases is characteristically unimodal). The rationale for the latter approach is that the position and shape of tuberculous reactions among apparently healthy, but infected individuals ought to be similar to the distribution of reactions among TB cases. Many tuberculin readers have a tendency of "digit preference" whereby reaction sizes ending with zero or five are recorded more often. Therefore, survey data may be corrected for digit preference before estimating prevalence.

Another method of analyzing tuberculin survey data is the "mixture model" approach based on Bayesian statistics.[66] This method operates by estimating the probability of true tuberculous infection at each mm of reaction size. Analysis using this model is undertaken separately for children with and without BCG scar. For analysis among those without scar, two component distributions are assumed; one for tuberculous infections and the other, for cross-reactions to infection with NTM. A third component attributable to BCG is assumed among children with BCG scar. This analysis can be undertaken using R software (version 2.4.1, http:/lib.stat.cmu.edu/R/CRAN) and ready scripts available at www.tbrieder.org.

ARTI can be computed from the estimated prevalence of infection and the trends, i.e. the average per annum change in the ARTI (α) between two surveys can be estimated.[67, 68]

The estimated ARTI[Φ] rates represent the overall effect of incidence of infectious TB cases, their average duration

---

[Φ] *Interferon GAMA Release Assay (IGRA) based tests for detecting tuberculous infection are not suitable for surveys to estimate ARTI, due to the difficulty of drawing blood by venepuncture among children in field conditions and its rapid transportation from peripheral areas, besides the high cost.*

of infectiousness and interactions between infectious cases and susceptible individuals. The average duration of infectiousness depends upon several factors, chiefly the efficiency of TB control program in term of case detection rate, treatment success and delay in diagnosis. Since, the extent of transmission of infection determines the total pool of infected people in the community, ARTI estimates give a fairly predictable estimate of new cases likely to emerge in the years to come.

In communities where efficiently functioning TB control programs are run with the high levels of case-detection and cure of smear-positive cases, the risk of infection declines. Therefore, the extent of per year decline in ARTI rates observed from repeat tuberculin surveys becomes a good gauge of program efficiency. It has been estimated that if at least 70% of incidence cases of smear-positive pulmonary TB are detected every year and 85% of them are cured, ARTI rates would decline by 7 to 11% per year.[40] In contrast, an increasing trend in ARTI points towards poor performance of control programs and/or several other epidemiological factors, such as an increase in HIV sero-prevalence in the community. It should be kept in mind that ARTI, which is estimated from the prevalence of infection among children might not be applicable to all age groups as the risk of tuberculous infection in different age groups may vary even if slightly and, is observed to be age dependent.

There are factors which may generate a bias in the estimates of prevalence of infection- boosting due to previous tuberculin testing, waning of tuberculin sensitivity with time, cross-reactivity to NTM, missing data on the risk of infection experienced by the children hospitalized at the time of survey or those who had died in the past. With a greater efficiency of DOTS programs, prevalence of infection among children falls faster.[56,69] These factors might lead to the absence of bimodality on the frequency distribution of reaction sizes contributing to ambiguities in deciding the anti-mode or mode. Such data from tuberculin surveys create difficulties in analysis. Tuberculin surveys may therefore primarily be useful for the study of trend in ARTI. There is a word of caution here too. Significant levels of migration in certain areas may also render the data on trends difficult to interpret.

INDIA—A CASE STUDY FOR MEASURING EPIDEMIOLOGICAL SITUATION AND TRENDS

A significant amount of community-based data has been generated over the years in India, even though such studies are operationally difficult due to the requirement of large sample sizes and huge amount of required resources in the terms of finances, time and highly skilled manpower. The data on prevalence, incidence and mortality obtained from such studies and other sources besides the WHO estimates and their trends are presented in this section.

Prevalence Surveys

The Indian Council of Medical Research (ICMR) conducted a nation-wide survey during 1955-58 to estimate the prevalence of PTB.[70] The study population was screened using MMR and one sputum sample and one laryngeal swab were collected from each of those showing any abnormal shadow. Findings of this large scale survey revealed that the average national level prevalence of bacteriologically positive PTB was similar in the rural and the urban areas of the country at 400 per 100,000 population, 80% of the cases lived in rural areas. Hitherto, TB was believed to be predominantly urban disease. This information was useful for planning the strategy and resources required for NTP, which was implemented across the country from 1962. Though the survey was not aimed at study of differences in prevalence between different areas, significant difference could still be observed, for example, between different cities.

A number of surveys have been carried out subsequently in different geographical locations. (Tables 36.2 and 36.3). There were some variations across the surveys in the definition of pulmonary symptoms. While two sputum specimens were collected from each eligible individual, some investigators examined sputum specimens either by culture or smear, others performed both. Similarly, there were variations in the methods used for smear microscopy—Ziehl-Nelson technique, fluorescent microscopy. Consequently, there was variation in definition of a bacillary case of PTB. Even though, the methods were not uniform across the surveys, the results had given reliable indicators on the magnitude of TB burden, which seemingly varied.

The trends in the prevalence of TB are available from some of these areas. Prior to the demarcation year of 1990, serial surveys were carried out in Tumkur, Madanapalle, rural Bengaluru, Chingleput and a defined area of Delhi.[20,21,71-77] Significant decline in the prevalence of TB was not observed over the years except in Madanapalle, which was the site of an intensified chemotherapy program. The progress towards MDGs from the base year of 1990 is thus far available only from Tiruvallur where three rounds of surveys carried out between 1999–2006 revealed a decline of about 12% per year in the prevalence of smear-positive, as well as culture-positive

PTB.[85] Whereas results from a survey carried out in Car Nicobar during 2001-02 showed an increase in prevalence when compared to a survey carried out there during 1986.[84] Considering the shortcomings in the availability of trends in the different parts of the country, baseline surveys have been carried out during 2007-2010 in six other sites (rural Bengaluru, Wardha, Faridabad, Mohali, Banda and Jabalpur). The preliminary results from these sites show large variation in the prevalence of disease across different sites.[88]

Although, the above mentioned surveys were not specifically designed to compare prevalence by age group and sex, the prevalence was generally found to be significantly higher among males with a male to female ratio from 2:1 to 5:1 in different surveys. This difference by sex was more pronounced after 35 years of age. More than half of the disease burden in females was concentrated in the reproductive age group of 20-44 years. The prevalence was also observed to increase with age, more so among males. Nearly half of the prevalence cases were concentrated in ≥ 40 plus years age group. The national level survey (1955-58) and the survey in the Wardha district (1982-88) also revealed an association between disease prevalence and socioeconomic conditions, as the prevalence was higher among those living in *kaccha* (mud) houses compared to *pucca* (concrete) houses.[70,78]

The estimates of prevalence of abacillary PTB and their time trends are not presented, there has been a greater variation in the techniques of interpretation of X-ray films across the surveys in different areas and during the different rounds of surveys in the same areas. Often, there is a tendency to overestimate the prevalence of abacillary TB during the surveys. Moreover, the standard procedure of giving a course of antibiotics to abacillary case before deciding on the nature of the X-ray lesion has never been followed during the surveys.

Cohort Studies for Measuring Incidence

A limited number of community-based studies on the incidence of PTB are available from India (Table 36.4). In rural Bengaluru, South India, the annual incidence of culture-positive PTB ranged between 79-132 per 100,000 population.

In Chingleput, the incidence of culture-positive PTB varied from 189 to 352 per 100,000 population. The incidence of smear-positive PTB varied from 113 to 157 per 100,000 population. Overall, there was an average decline of 4.3% per year in incidence of culture-positive PTB and 2.3% per year in the incidence of smear-positive PTB. In North Arcot, incidence of smear-positive TB was estimated at 1.1 per 1,000 population during 1981-83.[79] In Thiruvallur, incidence of smear-positive cases among adults between three surveys carried out between 1999 and 2003 was 126 per 100,000 population.[85] Passive case finding at the health centers was also included in this estimation, but there was no selective case finding as in Chingleput.

Incidentally, the above mentioned serial surveys in Chingleput were carried out as a component of a Randomized Control Trial (RCT), to estimate the protective efficacy of Bacille Calmette-Guérin (BCG) vaccine against bacteriologically positive PTB.[83,89] It was observed over the 15-year period of follow-up that BCG offered no protection against bacteriologically positive PTB among adults. Even though, a protective efficacy 27% against bacteriologically positive PTB was observed among children 1-9 years of age, it was not significant statistically.

Ratio Between Prevalence and Incidence

The ratio of incidence to prevalence of TB reflects the efficiency of TB control activities. During the pre-chemotherapy era, the average duration of infectiousness of a smear-positive case was found to be about 2 years, therefore, the ratio of incidence to prevalence was observed as 1:2. However, in Chingleput, this ratio was observed to increase from 2.5 to 4.2 between 1968 and 86.[20] This increase signified further accumulation of old cases attributable to increases in the duration of illness, diagnostic delays and poor treatment success rates. An effective implementation of DOTS strategy should decrease this ratio by decreasing the average duration of disease.

Annual Risk of Tuberculous Infection

A number of surveys were carried out in the country during the second-half of 20th century, to estimate ARTI among children. The estimated ARTI during most of the surveys varied between 1 to 2%. (Fig. 36.4).

However, except for two, the rest of these surveys were carried out in limited geographic areas of South India. Thereafter, four zonal level surveys were carried out in 2000-2003.[96] For this purpose, the country was divided into four zones, each zone consisted of contiguous states combined to encompass one-fourth of the country's population. Each zonal survey was carried out in 6-8 districts selected by Population Proportion to Size (PPS) method. The purpose of the surveys was to estimate ARTI among children without BCG scar and

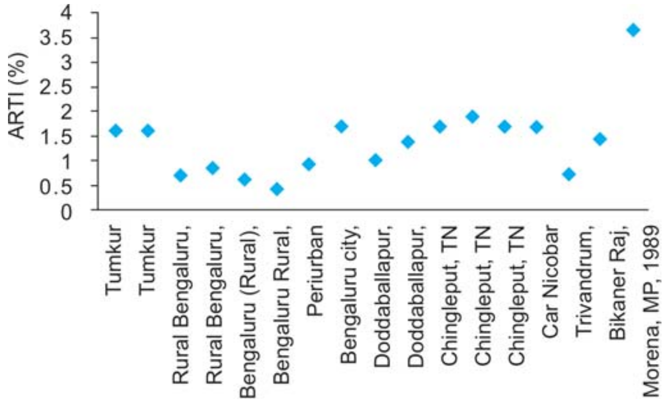

Fig. 36.4: ARTI in different parts of India, 1960-2000

1-9 years of age, in each of the zones. The estimated ARTI varied between 1% in Southern zone to 1.9% in Northern zone[96] (Fig. 36.5).

Survey findings also revealed higher rates of infection transmission in urban areas compared to rural areas.

Though the first zonal level surveys were designed to estimate ARTI among children without BCG scar, children with scar were also tuberculin tested. Data revealed that there was no statistical significant difference in the estimates of ARTI rates between children with and without BCG scar in 5-9 years age group.[63] A significant difference was however seen in 1-4 years age group. Earlier, tuberculin surveys were traditionally conducted among children with BCG scar, based on the observations of influence of BCG-induced tuberculin sensitivity, when BCG was given under research conditions or as special campaigns. Several tuberculin surveys have been carried out after the turn of the millennium (Table 36.5).[69,84,96,98-103] The results of no influence by BCG in later surveys could be attributed to low dose vaccine given immediately after birth under program conditions. These findings, however, should not be construed as indicating that BCG is not protective against childhood forms of TB, as no relationship has been found between tuberculin sensitivity induced by BCG vaccination and the protective effect of BCG.[97]

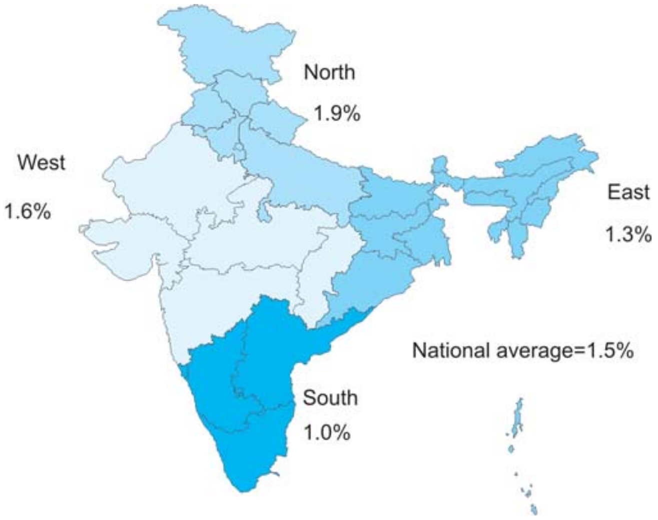

Fig. 36.5: First zonal level ARTI surveys, 2000-03

Note: The percentages quoted in the figure are best estimates of ARTI in respective zones demarcated here by different colors

Trends in ARTI are available from six defined geographical areas. During the pre-DOTS period, there was no decline in Chingleput and Doddaballapur while a small decline of 3% per year attributed to natural phenomena was observed in rural Bengaluru.[20,90,92] Trends available in the recent past from Tiruvallur district and Bengaluru city revealed a decline of 6% and 4% per year respectively (Table 36.6).[56,69,104]

TB-specific Mortality Rates

Direct estimate of TB mortality is available from a prospective cohort study carried out in rural Bengaluru during 1960-68 when annual TB-specific mortality rate was estimated at 80 per 100,000 population.[105] An estimated 50% of the annual deaths are presently notified under the vital registration system in the country.[106] However, a Sample Registration System (SRS) was initiated in 1969 to count the births and deaths in a nationally representative sample of villages and urban blocks.[107] The sampling frame for the selection of areas to be included in SRS and the numbers of sampling units to be selected is revised every ten years after the completion of each census. The SRS data provides useful information on crude birth and death rates and the infant and maternal mortality rates. The data on the causes of death is published as a separate report. TB accounted for about 6% of all deaths during 2001-03.[108] A verbal autopsy-based study in Chennai revealed TB mortality rate at 152 per 100,000 population among males and 43 per 100,000 among females.[109] A national level study to find out the COD for 1 million deaths is currently in progress.[54]

WHO Estimates

In the year 2008, there occurred about 2 million TB cases in India, which amount to 20% of the incidence cases worldwide.[1] There has been a significant decline in the prevalence of TB from 340 per 100,000 population during

1990 to 190 during 2008.[3] The TB mortality rates declined from 40 per 100,000 population in 1990 to 23 in 2008.[3] These trends may be related to a combination of improvements in living conditions on an average and the implementation of Revised National TB Control Programme (RNTCP) based on DOTS, and now the Stop TB Strategy. Treatment success of 80% and above has been consistently achieved among the cases treated by DOTS and there has been continuous improvement in case detection rates. During 2008, the overall case detection rate was 69% and the treatment success rate for the cohort of new smear-positive cases registered for treatment during 2007 was 87%.[3] However, the incidence has remained stable during this period at 170 per 100,000 population per year.[3]

Multidrug-Resistant TB

The study of proportion of MDR-TB cases and the proportion of all TB cases attributable to HIV infection is an integral part of the description of epidemiological situation of TB. Several drug resistance surveys conducted in India recently have revealed that about 2 to 3% of new PTB cases and 12 to 17% of retreatment cases are MDR-TB (defined as resistance to at least INH and rifampicin).[110,111] This amounts to 1,11,000 MDR cases emerging every year in India, which comprise about 30% of all MDR-TB cases globally.[111] In a study among patients from tertiary care centers, 4.6% of MDR cases were found to be Extremely Drug Resistant (XDR) defined as resistance to both rifampicin and isoniazid, as well as to any one member of the quinolone family and at least one of the parenteral second-line anti-TB injectable drugs, i.e. kanamycin, capreomycin or amikacin.[112] The sentinel surveillance of HIV seroprevalence among TB cases showed that about 6.7% of the incidence TB cases during the year in India were HIV positive.[3]

Prospects for TB Control in India

If changes in prevalence and mortality between 2001 and 2006 estimated as per WHO model continue in future, then MDG targets for India for these two parameters are likely to be met by 2015.[111] The average ARTI of 1.5% in the county computed during the nationwide survey in 2000-2003 implies that about 1,500 individuals for every 100,000 population acquire new tuberculous infection every year.[113] This adds to the total pool of infected people potentially at the risk of developing TB in future. Thus, new TB cases shall continue to emerge in large numbers for several years to come. However, there is reasonable evidence from tuberculin surveys in limited geographical areas about the declines in the transmission of infection as a result of DOTS. Therefore, it is possible that the incidence would start falling once the cohort of older people with the higher prevalence of infection is replaced by cohort of younger people with lower prevalence of infection.

Achievement of targets for case finding and treatment success consistently over next 10-12 years would lead to significant reduction in the disease burden. However, an increase in seroprevalence of HIV and multidrug-resistance TB is likely to have opposing influence on epidemiological trends of TB.

GLOBAL TRENDS OF TUBERCULOSIS

During the first half of the 18th century, TB mortality rates as high as 900 per 100,000 population per year were recorded in England. The TB mortality rates peaked in most Western European countries around the beginning of the 19th century and a few decades later in Eastern Europe.[38] In the 20th century, the morbidity and mortality rates declined considerably in most of the developed countries of North America and West Europe.[38,114] For example, the incidence fell by 58% in Denmark within a time period of 20 years from 1921 to 1940.[115] The trends were accompanied by a parallel decline in the risk of infection and consequently in TB among children. The ARTI rates fell at the rate of 5% or more per year in the most European countries.[116-118]

The decline was attributed to improvements in socio-economic and living conditions. The little information that is available from the developing countries revealed no downward trend during the first-half of 20th century.[118] For example, TB mortality in Alaska, accounting for about 35% all deaths remained constant at 65 per 100,000 population from 1920-1950.[119]

From the middle of the 20th century, the rate of decline in the North American and Western European countries hastened when chemotherapy for tuberculosis became increasingly available.[118] Some of these countries recorded declines of 10 to 15% per year in case notification rates and ARTI up to 1980s, underline the potential of success in TB control.[90,115, 116,118,119] There was more rapid decline among children and young adults. In contrast, the TB situation remained stable in most developing countries despite the introduction of chemotherapy.[118] This was primarily due to the poor implementation of anti-TB activities. The ARTI rates during this period were 50-100 times of that in developed countries.[118]

The declining trend of TB in the industrialized countries and in some of the middle-income countries witnessed a reversal after mid-eighties, as a result of the advent of HIV epidemic and other sociodemographic factors. These trends can be most appropriately illustrated by the TB situation in USA where, after a dramatic decline in the incidence of TB during most of the 20th century, there occurred a 20% increase in notification rates from 1985 to 1992.[120] Most of the increase occurred in the heavily populated urban areas, which had the highest numbers of immigrants from countries with high prevalence of TB. Significantly, the median age of persons with TB decreased from 49 years in 1985 to 43 years in 1992.[120] Additional factors responsible for the rising trend of TB were increase in cases of MDR-TB mainly in the urban and minority population, rising numbers of intravenous drug users with high prevalence of HIV infection, and non-adherence to chemotherapy by homeless persons.

Increase in the TB incidence was also observed in Eastern Europe primarily due to civil strife accompanied by economic difficulties and breakdown of health care and drug supply system.[115] While resurgence took place in the developed world after the years of continuous decline, there was further worsening of the TB problem in developing countries. The advent of HIV/AIDS epidemic in many countries was strongly associated with increasing TB incidence with maximum impact in countries with high HIV prevalence rates. There were 3-4 fold increases in case notifications in countries most affected by HIV, such as in sub-Saharan Africa over a period of 1-2 decades.[121, 122] HIV seroprevalence rates of more than 40% among TB cases are now common in some of these countries.[121, 122] TB became the most common opportunistic disease associated with HIV.[123] In most countries with high HIV prevalence, e.g. Zambia, there has been a decline in life-expectancy with concomitant increase in TB incidence.[124] High rates of HIV prevalence and TB reported from Northern Thailand and Southern American countries.[125,126] An increasing trend of HIV seropositivity rates among TB cases has also been observed in India.[127]

Fortunately, with the introduction of DOTS, under sustained control program, the TB rates have started declining again from the mid-1990s in the developed countries which had witnessed resurgence only about a decade earlier.[128] The decline in MDR-TB was in fact faster than in the drug-sensitive TB. Of late, the community-based studies in India and Indonesia have demonstrated significant declines in the prevalence of TB.[56,129] In China, which is the second highest TB burden country after India, a decline of 32% in prevalence of bacteriologically positive pulmonary TB has been observed between the two surveys carried out in 1990 and 2000.[59] A similar decline of about 30% in prevalence of bacteriologically positive pulmonary TB was observed between two surveys carried out in 1997 and 2007 in Philippines, another high burden country.[130] The annual WHO estimates also demonstrate a drastic reduction in prevalence in most countries of the world, after implementation of DOTS. Trends in Americas have been strongly correlated with coverage of prevalence with DOTS.[128]

Based on detailed analysis of notification data, the incidence of smear-positive TB in Peru is estimated to have declined at the rate of 6% per year between 1991 and 2000.[131] There are signs of decline in TB incidence in some of the areas where a reversal of HIV epidemic has been witnessed in the recent period. The declining trend in China and Peru is attributed to not only TB control programs, but also improvements in general health and socioeconomic status of their population.[128] The declining trends in TB incidence in some countries are related to life-expectancy, under-five child mortality rate (both are indicators of general health status) and measles vaccination coverage (indicator of health services).[128]

Risk Factors for Tuberculosis

Parvaiz A Koul, Nargis K Bali

INTRODUCTION

Tuberculosis (TB) develops as a result of the progression of primary infection, exogenous reinfection or endogenous reactivation. Risk of active disease is highest immediately (within 24 hours) after infection is acquired, the accepted principle being that the risk of disease is greatest within first 2 years following infection, which starts to level off after about 7 years, remaining low and unchanged over the following decade and usually during lifetime. Also, if the infection is acquired during childhood, the lifetime risk of progression from infection to disease is around 10%.[1] The development of tuberculosis in man is essentially a two-stage process in which a susceptible person exposed to an infectious TB case becomes infected and may later develop the disease. In individuals infected with *Mycobacterium tuberculosis*, any condition modifying the balance established in the body between the host's immune defences and the tubercle bacilli can have an impact on the risk of developing the disease. Different factors both "intrinsic" and "extrinsic" to the host can variously affect an individual's susceptibility to develop TB (Table 37.1).[2,3]

TABLE 37.1: Risk factors for tuberculosis

A. Underlying Medical Illness
  a. HIV infection
  b. Diabetes
  c. Transplantation
  d. Silicosis
  e. Malignancy
  f. Gastrectomy
  g. Jejunoileal bypass surgery
  h. Chronic renal failure
  i. Malnutrition
  j. Immunosuppressant/corticosteroid treatment

B. Sociodemographic Factors
  a. Age
  b. Overcrowding
  c. Homelessness
  d. Correctional facilities and prisons
  e. Intravenous drug abuse
  f. Alcohol abuse
  g. Immigration from endemic areas
  h. Smoking
  i. Poverty
  j. Malnutrition

C. Host Genetic Factors
  a. Polymorphism in NRAMP1 gene
  b. Vitamin D receptor gene
  c. Gamma interferon signaling
  d. TNF receptor gene

RISK FACTORS OF DEVELOPING TUBERCULOSIS

Some of the known important risk factors are discussed below:

Underlying Medical Illnesses

Human Immunodeficiency Virus (HIV) Infection

Worldwide, tuberculosis is the commonest HIV associated disease of public health importance and HIV infection is the strongest risk factor for the reactivation of tuberculosis infection and progression to active disease. The effect of the HIV epidemic on TB has been well-documented, with incident rates of TB, particularly in Africa, rising rapidly as a result of HIV.[4] Among

9.27 million incident cases of TB in 2007, an estimated 1.37 million (14.8%) were HIV-positive. This number, although double the estimate of 0.7 million cases in 2006, that WHO published in 2008[5] does not mean that the number of HIV-positive cases of TB doubled between 2006 and 2007; rather, new data that became available during 2008 have been used to estimate both the number of HIV-positive TB cases in 2007 and to revise the estimates of the number of such cases that occurred in previous years. The global number of incident HIV-positive TB cases is estimated to have peaked in 2005, at 1.39 million. In 2007, as in previous years, the African Region accounted for most (79%) HIV-positive TB cases, followed by the South-East Asian Region (mainly India) with 11% of total cases, South Africa accounted for 31% of cases in the African Region.[4] Around 0.45 million patients co-infected with HIV died of TB in 2007; tuberculosis is also the leading cause of death in patients living with HIV, even in those receiving antiretroviral therapy.[4,6]

Direct estimates of the prevalence of HIV in TB provide strong evidence that the risk of developing TB in HIV-positive compared with HIV-negative (the incidence rate ratio or IRR) is higher than previously estimated. The IRR was estimated as 20.6 (95% Confidence Interval (CI) 15.4–27.5) in 2007 in countries with a generalized HIV epidemic (i.e. countries where the prevalence of HIV was above 1% in the general population), and 26.7 (95% CI 20.4–34.9) in countries where the prevalence of HIV in the general population was between 0.1% and 1%; and 36.7 (95% CI 11.6–116) in countries where the prevalence of HIV in the general population was less than 0.1%. These IRR estimates compare with previous estimates of 6, 6 and 30, respectively.[4]

The impact of HIV infection on tuberculosis pandemic is multifold. The risk of active TB doubles in the first year of HIV coinfection while the risk of developing active disease in those who have Latent TB Infection (LTBI) is 10% per year.[7,8] However, the impact of HIV infection on TB is not limited to the reactivation of LTBI. It has been shown in several studies that HIV-infected patients, who at any point of time, become infected or reinfected with *M. tuberculosis,* progress faster to full-blown disease than HIV-negative individuals who develop tuberculosis.[9-12] Thankfully, however, HIV-infected tuberculosis patients do not appear to be potent transmitters of *M. tuberculosis*, the fact being substantiated by numerous household contact studies which have consistently shown that HIV-infected patients with tuberculosis are less likely to transmit tubercle bacilli to their close contacts than HIV uninfected individuals with tuberculosis.[13-16] HIV-TB coinfected individuals have reduced survival[17] and are at higher risk for subsequent opportunistic infections.[18] In overcrowded and poor living conditions, the combined effect of the two epidemics is magnified as evidenced by more than 2,000 per 1,00,000 population prevalence rates in certain South African communities.[19,20] Added complications in coinfected individuals include drug-resistant TB and immune reconstitution inflammatory syndrome.[21] The emergence of drug-resistant TB in countries with a high HIV prevalence poses an additional public health threat, not only to people with HIV, but also to the broader community.[8]

Tuberculosis is the prototype of infections that require a cellular immune response for their control.[22] All persons have a native population of lymphocytes, mostly $CD4^+$ cells bearing αβ T-cell receptors, capable of recognizing mycobacterial antigens, processed and presented by macrophages. In tuberculin-positive patients (those who have been infected with *M. tuberculosis*), endogenous foci may reactivate repeatedly and active CD4 surveillance is mandatory to maintain quiescence. As the CD4 levels fall in HIV-infected patients, both in early (CD4 > 300 cells/mm^3) and late (< 200 cells/mm^3) stage of the disease, the chances of both endogenous reactivation and exogenous reinfection increase substantially. The earliest description of tuberculosis in Acquired Immunodeficiency Syndrome (AIDS) patients emphasized the increased risk of reactivation of remote infection due to progressively compromised immunity. Studies carried out in Haitians, all of whom were likely to be infected with *M. tuberculosis* in childhood, showed that AIDS was associated with development of active tuberculosis in 60%.[23] Subsequent studies in methadone clinic patients in the New York City who were HIV-positive and tuberculin-positive revealed, that tuberculosis developed in 8% of the clinic patients per year.[8] These studies thus suggest that nearly all tuberculin-positive patients with HIV infection eventually develop active tuberculosis unless either HIV or tuberculous infection or both are effectively treated or some other fatal complication of AIDS occur.

The clinical picture of tuberculosis in HIV infection is defined by the degree of immunocompromise.[24] The clinical spectrum ranges from a negative tuberculin sensitivity test result, greater incidence of extra-pulmonary disease (>50%), middle and lower lung zone involvement and absence of cavitation to positive tuberculin test result, cavitatory disease (less than 10% to 15%), predominant extra-pulmonary involvement and a diffuse rapidly progressive disease, which is often fatal. Management of these patients may be further complicated by concomitant intravenous drug use and homelessness. Failure to isolate and treat these patients under supervision is a major contributor to the outbreak of Multidrug-Resistant Tuberculosis (MDR-TB) in this population. Directly Observed Treatment Short-Course (DOTS) is especially important in coinfected individuals to ensure drug compliance, which is otherwise poor.

Diabetes

Physicians have noted the relationship between diabetes and tuberculosis since ancient times; perhaps the earliest was by Susruta, the Indian physician in 600 AD. Avicenna too had noticed phthisis complicated diabetes and that the presence of diabetes resulted in an increased risk of developing TB.[25] However, it has gone unnoticed and in the most recent national guidelines, has only been mentioned as something needing more research.[26] If not acknowledged appropriately, the association is believed to pose a threat, both to the successful TB control and to the treatment of diabetes.[27] Several large studies have demonstrated the increased risk of tuberculosis in patients with diabetes. In Korea, a 3-year longitudinal study involving 8,00,000 civil servants showed that the risk-ratio of TB in diabetic patients versus non-diabetic controls was 3.47 (95% CI 2.98–4.03).[28] From the UK General Practice Research Database, which included records from over 2 million patients, Jick and colleagues[29] identified all cases of TB reported between 1990 and 2001 and found that the adjusted odds ratio (adjusted for age, sex and practice) for TB was 3.8 (95% CI 2.3–6.1) for diabetic patients compared with those without diabetes. In Hong Kong[30], in a 5-year study of 42,000 elderly individuals, the adjusted hazard of active TB was higher in diabetic patients than in individuals without diabetes (1.77; 95% CI 1.41–2.24), but this increased risk was only present in those with hemoglobin A1c concentrations greater than 7%. Indeed, a recent large meta-analysis[31] showed that diabetic patients were 3.1 times (95% CI 2.27–4.26) more likely to have TB than controls with higher effect sizes in non-North American population. The presence of diabetes was found to increase the risk of contracting tuberculosis by 1.5 to 7.8 fold in various studies, being highest in the younger age group without any influence of gender.[32,33] Stevenson et al.[34] estimated that the population attributable risk for tuberculosis from diabetes was 14.8% of incident tuberculosis cases and about 20% of sputum-positive cases in India. Insulin dependence suggestive of a severe diabetes and a higher HbA1c as a marker of poor glycemic control have been found to be associated with a higher risk of tuberculosis.[32,35] In the setting of the increasing overlap of population at risk for both diseases, the combination of TB and diabetes mellitus represents a worldwide health threat.[36]

TABLE 37.2: Possible mechanisms underlying increased risk to tuberculosis in diabetics

1. Impaired phagocytic activity of monocytes/macrophages
   - Impaired chemotaxis
   - Impaired phagocytosis
   - Impaired activation
   - Impaired antigen presentation by phagocytes in response to *M. tuberculosis*
2. Altered polymorphonuclear cell function
3. Impairment in T-cell production of gamma interferon
4. Impaired T-cell growth, proliferation and function
5. Diabetic microangiopathy induced alteration of local response.

Several mechanisms have been put forward to explain the phenomenon of increased risk of TB in diabetes (Table 37.2). Alterations in pulmonary immune cell function reduced activity of monocytes/macrophages; impaired activation, chemotaxis and antigen presentation leading to ineffective phagocytosis of intracellular organisms, reduced lymphocyte function and impaired T-cell growth, proliferation and function may all be responsible. The varied effects of diabetic microangiopathy on the capillaries of alveolar septa and arterioles may also affect the local response to infection.[37-39]

Evolution of the symptoms and signs of tuberculosis in diabetic patients are same as that in non-diabetic patients. The coexistence is expectedly known to result in greater complications. The mortality of tuberculosis has been reported to be higher when complicated by diabetes and the disease tends to have increased severity characterized by cavitations, lower lobe involvement and smear positivity.[40,41] A higher risk of multidrug-resistant tuberculosis has also been reported in diabetics even as some other studies have shown no significant risk of drug resistance.[42-48]

It is unclear, whether the aggressive management of Diabetes Mellitus (DM) would improve treatment response. Since the causes of death are not reported in most studies, we do not know whether excess mortality is explained by increased severity of TB in diabetic or by the existence of comorbidities attributable to diabetes mellitus compounded by more advanced age.[36] People with DM may also be important targets for interventions such as active case finding and the treatment of latent TB. [27]

Organ Transplantation

Procedures employed to minimize the risk of rejection in transplant recipients produce an alteration of immune status in them, predisposing such patients to infections caused by both common and rare organisms. Tuberculosis associated with organ transplantation, occurs in an estimated 0.35 to 6.5% of organ recipients post-transplantation in the United States and Europe, the risk of TB in transplant recipients is estimated to be 20 to 50 times higher than in general population and mortality rates vary from 20 to 40%.[49] Nearly 49% of the US transplant recipients with TB have disseminated disease and 38% of them die.[49]

Risk factors for the development of TB in transplant recipients include previous TB infection, immunosuppressive treatment with OKT3 or anti-T cell antibodies, diabetes mellitus, chronic liver disease and coexisting infections.[49-52] Tuberculosis is rare after Hematopoietic Stem Cell Transplantation (HSCT) and ten times less frequent than in Solid Organ Transplantation (SOT), as HSCT recipients do not receive lifelong immunosuppression. Undergoing transplant in a country with a high endemic rate of TB is also an important risk factor.[53] Unrelated or mismatched related transplants, Graft-Versus-Host Disease (GVHD) and total body irradiation increase the risk of TB reactivation after HSCT.[54] The majority of TB cases among organ transplant recipients are caused by the activation of LTBI in the recipient. Once immunosuppressive medications are started to prevent organ rejection; a minority are attributed to donor transmission. In one international study, 4% of TB infections in recipients were considered donor derived.[49]

Clinical aspects of the disease includes a high incidence of extrapulmonary or disseminated tuberculosis (49%).[49] Among extrapulmonary cases presentations include gastrointestinal, hepatic, skin, muscle, osteoarticular, genitourinary, ganglia, central nervous system and other more uncommon sites of disease such as the larynx, tonsils or eyes.[49,55] In transplant patients, TB should be considered in the differential diagnosis of persistent fever, pneumonia, meningitis, septic arthritis, pyelonephritis, septicemia, graft rejection or bone marrow suppression. Clinicians should recognize that the presence of an unusual constellation of symptoms, particularly during the first few weeks after transplantation, raises the possibility of donor-transmitted infection or activation of LTBI. Even with a high index of suspicion, TB in an organ recipient can be challenging to diagnose 75 to 80% of organ recipients who developed TB, had a false-negative pretransplantation Tuberculin Skin Test (TST).[56] It is important to recognize that in this immunosuppressed population, symptoms of TB might be attributed to other potential complications, including organ rejection or other infectious diseases. Diagnosis of TB in an organ recipient, in the absence of clear risk factors or other evidence from pretransplantation screening, should prompt the investigation of possible transmission from the donor. Other recipients from a common donor might be at risk and should be evaluated for TB.

Investigation of epidemiological risk for LTBI is mandatory in transplant recipients. LTBI can be evaluated through TST. The sensitivity of TST is lower in immunocompromised hosts, induration of ≥ 5 mm, is considered positive.[57] In SOT, around 20% of the recipients test positive, the positivity being greater in liver transplant recipients (around 70%).[49] Positivity of 23% was observed among HSCT recipients.[58] It is important to highlight that the specificity of TST may be impaired in transplant patients from developing countries since a positive test may indicate infection with nontuberculous mycobacteria or previous vaccination with the Bacille Calmette-Guérin (BCG).[59] The role of TST, as well as of the new Interferon-Gamma Release Assays (IGRAs), such as the QuantiFERON test, in the evaluation of LTBI in transplant recipients has not been fully investigated. A recent meta-analysis suggests that IGRAs may be more sensitive than TST in immunocompromised patients suspected of having TB.[60]

Pretransplant evaluation of epidemiological risk of TB should be made for donors and recipients. Previous TB infection or contact with infected persons should be particularly investigated, as well as careful radiological evaluation should be done to check for images suggestive of previous healed TB.[61] Tuberculin skin test with 5 tuberculin units of purified protein derivative is recommended for transplant candidates, a negative test should not exclude the possibility of LTBI. If LTBI is suspected, treatment with Isoniazid (INH) should be started. A full 9-month course is recommended. Alternative schedules may be considered on individual basis. In HSCT recipients, the combination of pyrazinamide and rifampicin has shown significant liver toxicity and its use is not recommended.[62]

Silicosis

Silicosis, a fibrosing lung disease caused by the inhalation and deposition of crystalline silica particles, is the most prevalent pneumoconiosis.[63] The risk of developing pulmonary tuberculosis is reported to be 2.8 to 3.9 times higher for patients with silicosis than for healthy controls.[64-66] Patients with silicosis are also at a higher risk for extrapulmonary tuberculosis, the estimated risk being about 3.7 times higher.[65,67]

Local alterations in the lungs together with unfavorable conditions in the mines, inability to diagnose the disease rapidly and the high prevalence of TB in the population, are some of the factors responsible for the high incidence of this disease in this group of people. Important local alterations include the impairment of macrophage function (which plays a major role in the pathogenesis of the disease). Sublethal doses of silica dust also affect the ability of macrophages to inhibit the growth of *M. tuberculosis*.[68] Silica is reported to modify the immune response of the lungs, impair the metabolism/function of pulmonary macrophages and with frequent exposure, cause macrophage apoptosis.[67,68] These findings are consistent with observations that the incidence of tuberculosis is higher in dust-exposed workers, even in those without established silicosis, than in workers not so exposed. Surfactant protein A is also found to be high in BAL fluid of patients with silicosis. An excess of this protein seems to be associated with higher susceptibility to tuberculosis, possibly because it allows mycobacteria to enter the alveolar macrophages without triggering cytotoxicity and inhibits the formation of reactive nitrogen species by the activated macrophages.[69,70] The tubercle bacilli are also believed to remain encapsulated within the silicotic nodules, which would be responsible for the reactivation of tuberculosis in such patients.

Diagnosis of tuberculosis in silicotic patients is difficult since the symptoms are nonspecific. Moreover acid-fast stains of sputa of these patients are usually negative, probably because the tubercle bacilli do not reach the bronchial tree due to fibrotic changes. Chest roentgenogram can be of great value in the diagnosis. Radiographic criteria strongly suggestive of tuberculosis include the appearance of new infiltrates, cavities, pleural effusion, coalescence of nodules and development of bronchial stenosis.[68] Patterns suggestive of silicotuberculosis have also been recognized on chest CT scans. The principal findings consistent with active tuberculosis superimposed on silicosis are thick-walled cavities, consolidations, images presenting a tree-in-bud pattern, nodular image asymmetry and rapid disease progression.[71-73]

Longer therapeutic regimens with conventional antitubercular drugs are employed for the treatment of tuberculosis in these patients; the longer duration is necessitated because of the low penetration of the drugs into silicotic nodules. A study conducted in Hong Kong showed that 22% of the patients in the 6-month therapy group had bacteriological relapse in comparison to 7% relapses seen in patients in the 8-month therapy group, thus suggesting that the standard 6-month short course therapy is inadequate for these patients.[74] As a general recommendation, the sterilizing phase in these patients should be prolonged and they should be treated for at least 9 months. Moreover, therapy with rifampicin and isoniazid must be given for a minimum of 12 months, if pyrazinamide is not incorporated in the regimen.[68] Preventive chemoprophylaxis with INH has also been considered of great value in reducing the rates of active disease. One such study compared the treatment of 825 silicotic patients with 2,408 untreated silicotic patients. It was shown that preventive therapy with INH decreased the risk of developing active tuberculosis from 2.66 to 0.32%.[68]

The American Thoracic Society recommends that tuberculin skin tests should be performed in patients with silicosis. In cases of positive results (induration $\geq$10 mm) and after excluding active tuberculosis, the Society recommends that chemoprophylaxis should be instituted, using one of the four possible regimens: Isoniazid for nine months; isoniazid for six months; rifampicin and pyrazinamide for two to three months; or rifampicin for four months. The determination of bilirubin and hepatic enzyme levels in the initial evaluation is indicated only for individuals considered to be at high-risk for liver disease such as alcoholics, pregnant women and HIV-infected individuals.[57]

Malignant Disease

The synchronous occurrence of tuberculosis and carcinoma is unusual and the association of the two has baffled surgeons and physicians for over two centuries. Bayle first described the association of tuberculosis and carcinoma in 1810. He described “cavitation cancereuse” as one of the six types of tuberculosis, which appears to be the first published description of coexistence of the two.[75] The association of tuberculosis and cancer has been recorded in most of the organs. Kaplan et al. (1974)[76] reviewed 58,245 patients with cancer and identified 201 cases of coexisting tuberculosis. The highest prevalence was seen in patients with Hodgkin’s disease (96/10,000 cases) followed by lung cancer (92/10,000), lymphosarcoma (88/10,000) and reticulum cell sarcoma (78/10,000). Hematological malignancies have a higher incidence of tuberculosis than solid organ cancers.[77,78] Patients with hematological malignancies have impaired immunity, partly due to the disease process itself and partly due to cancer treatment, including chemotherapy, radiotherapy, long-term corticosteroid regimes, etc. Patients with leukemia are more prone to develop disseminated or extrapulmonary disease as compared to those with other hematological tumors.[77,79] Patients suffering from hairy cell leukemia have increased chances of developing tuberculosis, with incidences as high as 50%.[80] Lymphomas, notably Hodgkin lymphoma also placed an individual at greater risk of having these manifestations, although extrapulmonary tuberculosis in these patients is usually a focal disease.[81]

Tuberculosis in solid organ malignancies is mainly pulmonary, extrapulmonary/disseminated disease being less common.[77] Highest incidence has been seen in head and neck cancers, lung cancers and gastrointestinal malignancies.[77,81] In a recent case control study from Korea, the incidence of active tuberculosis was 3.07 per 1,000 persons per year against 0.7 amongst controls, showing an increased risk of developing tuberculosis (incidence ratio of 4.46).[82] The authors concluded that immune suppression by cancer or by anticancer chemotherapy increased vulnerability to reactivation of TB, especially in cancer patients with old healed TB. Lung cancer and pulmonary TB have been known to coexist. In some series, the relationship between these two entities was found to be more frequent than other associations.[77] The location of tuberculosis and lung cancer can either be same or different. Interestingly, if HIV infection is associated with lung cancer and tuberculosis, a normal radiographic pattern can be seen. Except for the increased incidence of the disease, TB in cancer patients does not seem to have different characteristics as compared to the general population.[77] A more severe pattern of disease is noted if cancer and tuberculosis appear in a sequential pattern, the reason being a greater debilitation of the patient during cancer.[77]

Gastrectomy and Jejunoileal Bypass Surgery

Subtotal gastrectomy and other gastric surgical procedures have been reported to be associated with an increased risk for tuberculosis since 1920s. The association was initially recognized at a time when gastric resection was widely performed for the treatment of refractory peptic ulcer disease. In recent decades, following the introduction of histamine type 2 blockers and proton pump inhibitors, gastric surgery has come to play a minor role in treating peptic ulcer disease. However, evidence that gastrectomy predisposes to the increased incidence of tuberculosis is highly suggestive, but not conclusive. Recent data suggest that gastrectomy patients are more predisposed to develop tuberculosis with an estimated two-to five-fold relative risk.[83-86]

Jejunoileal bypass surgery has been used increasingly in the recent decades to cause weight loss in patients of morbid obesity who do not respond to less drastic weight reduction measures. The average annual incidence of tuberculosis among bypass patients has been reported to be 27- and 63-fold higher than the incidence in comparison population.[87,88] Presumably, patients who are at greatest risk of developing tuberculosis are those who are already infected with tuberculosis at the time of the operation. However, none of the published reports provides data on the incidence or prevalence of disease among those infected or those uninfected, preoperatively. Nonpulmonary tuberculosis accounts for only 15% of the total cases in the general population, but 82% of cases in bypass patients have involved nonpulmonary sites. The reason for the increased risk of tuberculosis after bypass operation is unknown. Many patients become protein and zinc deficient postoperatively; both conditions are reported to adversely affect the cell-mediated immune responses.[89] The pathogenesis of the increased risk for tuberculosis after gastrectomy and bariatric surgery remains speculative. Confounding, attributed to factors, such as age, poverty, crowded living conditions, heavy ethanol consumption, nosocomial infection after surgery, severe weight loss caused by malabsorption and alkaline reflux gastritis, has been proposed.[83,84] The most widely cited hypothesis is that the increased risk of tuberculosis is attributed to rapid weight loss, malnutrition, and in some individuals, malabsorption. Tuberculosis occurs frequently in persons with protein-calorie malnutrition and resultant impaired cell-mediated immunity.[90]

As per the ATS/CDC guidelines,[57] individuals with weight loss of more than 10% of ideal body weight and those with gastrectomy or jejunoileal bypass surgery are considered at increased risk and should be offered treatment for latent tuberculosis infection if they have a PPD skin test reaction of 10 mm or more induration. Nine months of INH is now the preferred regimen for treatment of latent tuberculosis infection for most persons. Clinicians caring for patients, who have had gastric bypass surgery, need to be aware of the increased risk of tuberculosis in this patient population. Prompt diagnostic evaluation with chest roentgenogram, sputum examination, tissue biopsy and other appropriate studies should be initiated in patients with unexplained malaise, fever, cough and lymphadenopathy. In particular, a high level of clinical suspicion is needed for the diagnosis of extrapulmonary tuberculosis. Finally, because of potential problems with the malabsorption of oral drugs in patients after weight-reduction surgery, treatment should be coordinated with experienced tuberculosis control staff and monitoring of serum drug concentrations should be considered.

Sociodemographic Factors

Overcrowding

The most important determinant of infection is the closeness and the infectiousness of the source. *M. tuberculosis* infection is usually airborne; almost all infections are due to the inhalation of droplet nuclei that are infectious particles aerosolized by coughing, sneezing or talking. These particles are dry while airborne, remain suspended for long periods, get inhaled and reach terminal air passages. A sneeze can generate up to 40,000 droplets, which can evaporate to produce droplets of 0.5–12 mm in diameter. A cough can generate about 3,000 droplet nuclei, the same number as talking for five minutes (from Elsevier journal). A single cough, talking for five minutes and sneezing can generate equal number of droplet nuclei, which may be equal to 3,000 infectious droplet nuclei, or more.[91] The air in a room, occupied by a person with pulmonary tuberculosis, may remain infectious even after his/her absence.

Pulmonary tuberculosis fortunately is a disease with low infectiousness. Generally, prolonged contact and multiple aerosol inocula are required to establish infection. However, *M. tuberculosis* strains may vary widely in their transmissibility. In an outbreak in Kentucky, it was seen that people were infected in spite of the brief casual contact with the index case.[92] Closed spaces with little or no air circulation at all, favors the spread of tuberculosis. In USA, around 27% of household contacts of smear positive cases became infected, whereas rates as high as 80% were seen to occur in closed environments.[93]

Homelessness

With estimated prevalence of 1.6% to 6.8%, homelessness is regarded as one of the important risk factors for the development of tuberculosis.[94] The factors that contribute to an increased risk for tuberculosis among homeless persons include insufficient access to preventive services and health care as a result of financial, geographical and cultural barriers. Point prevalence of active TB as high as 968/1,00,000 homeless adults has been reported, nearly 100–300 times the nation wide prevalence.[95] Among homeless persons, the increased prevalence of conditions, which can suppress the immune system (like HIV infection, poor nutrition, untreated diabetes, COPD, alcoholism, illicit drug use and psychological stress) may increase the risk for active tuberculosis if infected.[96-99] Homeless persons also lack access to good health care and are highly mobile, they do not complete TB therapy and the likelihood of relapse, drug resistance and further transmission of tuberculosis among shelter residents thus increased. [97,99-101]

Clinical characteristics of TB in this group are similar to those in the general population and variations, if any, are due to the presence of concomitant factors such as HIV infection. Treatment of tuberculosis in this group of people should be using common therapeutic regimes.[94] Measures to curtail the spread of infection in these settings should be directed at rapid diagnosis and treatment of infectious cases, since establishing an effective prevention program is difficult in shelters.[102,103] Structural measures in shelters have also been considered as useful to prevent transmission of the disease; use of ultraviolet lamps to disinfect air and enhanced ventilation systems to reduce airborne transmission of the disease in some of them.[94] As seen with drug abusers, outcome of these homeless is dependent on compliance of therapy, which as expected is very low. DOTS is indicated for these difficult cases. Several incentives have been recommended, aimed at increasing the adherence to therapy, such as travel tickets, food, clothes or even money and have proven to be effective in increasing the compliance to drug therapy amongst these patients.[94]

Correctional Facilities and Prisons

Tuberculosis is a problem in correctional facilities and prisons; 3.7% of all the cases of tuberculosis in the United States in 1996 occurred amongst the residents of correctional facilities, with incidence rates of new cases in prison systems as high as 200 per 1,00,000 against the general population incidence of 8.0 per 1,00,000.[104-109]

Transmission of tuberculosis from prisons into surrounding communities has also been documented and therefore, correctional facilities may be important reservoirs of infection.[106] A prison was potentially linked to 9% of a state's tuberculosis cases during a 5-year period.[106] Incarcerated inmates have high rates of substance abuse, HIV infection, latent tuberculous infection, low socioeconomic status and other risk factors associated with active tuberculosis and hence have multiple factors operating for a higher risk of developing TB.

Drug Abuse

In recent years, drug abuse has emerged as a significant risk factor for the development of TB. Close association between HIV infection and intravenous drug abuse makes it difficult to differentiate between the independent roles of the two risk factors in the progression of TB. Apart from HIV infection, other factors that put drug abusers at increased risk include malnutrition, bad hygienic practices, antisocial behavior (e.g. criminality, auto-medication, and trading of pills to obtain money or drugs). Relation between tuberculosis and intravenous drug abuse has been well-known for many years.[104-113] A positive TST has been reported in up to 44% of HIV negative IV drug users and tuberculous disease has been reported in 6.8%.[104,105] On the other hand, several studies have shown drug abuse to be a statistically significant risk factor for tuberculosis in the general population.[106,107]

In HIV-infected drug abusers, the effects of HIV infection on the immune system often over-shadow other possible defects, which are contributory to increased risk of tuberculous disease. Nonetheless, immune defects can be found in HIV non-infected patients too. Due to the presence of concomitant HIV infection and several other infections, a high index of suspicion is required to diagnose tuberculosis in intravenous drug abusers. It should be a dictum to rule out tuberculosis in any such patient who presents with fever.[114] Screening of these patients for TB is also difficult owing to their anergy status because of HIV infection. A single skin test has previously been reported to be an unreliable predictor of development of TB and as such is not advocated in this patient population.[115] Instituting chemoprophylaxis in infected patients has been proved to prevent the development of active disease.[116-118] However, the same does not hold true for HIV anergic patients, in whom chemoprophylaxis does not reduce the incidence of disease; hence it is not indicated in these cases.[110,118]

Treatment of active disease has also been shown to be effective with some modifications in HIV patients keeping in view the possible drug interactions among the antiretroviral drugs and the anti-tubercular drugs.[16,44] Another major issue in treatment is that of non-compliance, which leads to increased chances of therapeutic failure among them with prolonged infectivity, increased rates of transmission and development of drug-resistant strains.[119] Measures for ensuring compliance in this group of patients have included forced confinement during treatment, but by far is the most effective and promising strategy.[119]

Alcohol Abuse

Alcoholism and alcohol intake are closely associated with tuberculosis.[120,121] In one hospital-based study, 49% prevalence of alcoholism was seen in patients with newly diagnosed tuberculosis.[122] The rate of active TB among alcoholics and drug abusers was 28 times higher than in general New York City population.[120] Alcohol intake was found to be associated with increased risk as well as poor compliance to treatment. These facts call for alcohol intervention campaigns along with tuberculosis control programs.[123]

Age

Among persons with tuberculous infection, rates of occurrence of diseases vary markedly with age. The case-rates are considerably increased amongst infants, young adults and elderly subjects. The reasons for the variations in age are as yet undetermined, but may relate to influences on the effectiveness of the immune response. Infection acquired early in life can progress to typical disease as the age advances. In the past, almost all patients were adolescents and young adults, but the recent years have witnessed a marked change in the clinical pattern of disease.

Infection in infants often results in disease; the younger the patient, the greater is the risk of progressive disease, until the age of 5 years. From this age onwards until puberty, there is relative resistance to the development of progressive disease, but not to infection. Disease confined to lungs in this age group usually heals spontaneously. Nonetheless, lymph nodes and bones may be involved. Short-term prognosis in these patients is good, although the frequency of relapse with chronic cavitary TB is high, especially during the more disease prone periods of adolescence and young adulthood.[118] Clinical disease that develops in adolescence and young adulthood may resemble childhood infection, but with less parenchymal and hilar calcification, this being particularly the case in dark-skinned races and immunocompromised patients, including those with AIDS.[24] Disease in this age group appears as chronic upper lobe tuberculosis with no clinical features of childhood disease. Tendency towards apical cavitation immediately after childhood infection appears after puberty and is marked in young adults.[57] Mostly, pulmonary TB in this age group is due to recent new infection rather than due to the progression of childhood infection, which is being substantiated by the fact that most young people in industrialized countries are tuberculin negative.

Infection acquired during the middle years of life has a much better prognosis, both long and short-term, than infection acquired in teens and in early 20s, presumably because of a reduced tendency to tissue necrosis.[118]

The incidence among women peaks at 25 to 34 years of age, rates being usually higher in women in this age group, while in older age groups, the opposite is true.

Immigration

Prevalence of tuberculosis is higher in the African and the Asian countries. Migratory movements of people between countries have become more frequent, favoring the transmission of infectious diseases from one place to another. These unrestricted movements from high prevalence areas can affect the control programs of other countries. As a matter of fact, immigration has been considered as a major cause of resurgence of tuberculosis in the Western countries.

Illegal immigration poses more threats to the control of potentially infected population. A study conducted in Spain showed that 78% were amongst illegal immigrants with active disease. Other factors that complicate the management of TB in this population include the language barriers, overcrowding, poverty, fear to seek professional advice and frequent imprisonment. All these factors affected compliance since adherence to therapy was even lower in infected patients without active disease.[124] However, strict follow-up and other complementary measures (e.g. use of patient's language for examination) increased the compliance of tuberculous patients to 78%.[124,125]

The potential transmission of tuberculosis from immigrants to local population is a theoretical risk. A molecular epidemiology analysis, making use of Restriction Fragment Length Polymorphism (RFLP) and spoligotyping, found only nine minor clusters in both Danish and immigrant patients, thus depicting only minor transmission between these population.[126] However, many other clusters were found suggesting the existence of predominant strains between immigrants and transmission between them.[125,126] A possible explanation is the low social contact between these two communities. Several other reports suggest that tuberculosis in immigrants is the result of reactivation and not of primary disease due to recent infection.[113,126-128] Drug resistance is an additional problem in infected immigrants on account of the multidrug resistance in their native countries. Antimicrobial testing may hence be indicated in such patients for appropriate therapy.

Others Risk Factors

There are numerous other factors that favor the progression of infection to active disease, notable among them being smoking, poverty and malnutrition, renal failure, immunosuppression and host genetic factors. Each of these factors places an individual at an increased risk of developing tuberculosis; nonetheless even in the same person, interplay of all or some of the above mentioned factors are seen on occasion.

Tobacco Smoking

An association between tobacco smoking and tuberculosis has been debated for over a hundred years and there is considerable evidence confirming the presence, strength and consistency of this association and the different levels at which it operates. Recent research demonstrates a direct connection between smoking and TB. Smoking increases the risk of latent TB infection by nearly two times, as well as increasing the risk of active TB by around two and a half times.[129] The basis of these findings was a large-scale meta-analysis, in which studies from 14 different countries were assessed.[129] Other research has produced similar results, with smokers having a relative risk of around twice that of nonsmokers for acquiring TB.[129-131] Smoking has also been found to lead to increased severity of the disease, longer hospital stays and decreased survival rates.[132,133]

Many physical and social factors associated with cigarette smoking are also known to contribute in the development of tuberculosis;[130] immunosuppression, old-healed fibrotic lesions, unemployment, and lower socioeconomic and education status being some of them. It has been shown that tobacco smoking causes pulmonary impairment and smoking would be expected to increase the risk of pulmonary impairment due to tuberculosis.[134] Indoor air pollution from passive smoking is another strong factor in causing tuberculosis. Chronic exposures to smoke from biomass fuels is another contributory risk for tuberculosis, as well as other lung diseases particularly in immigrants.[135-139] A history of such biomass smoke exposure may be an important risk factor for pulmonary tuberculosis and abnormal pulmonary function following its microbiological cure. However, these possibilities need to be substantiated with further research.

Poverty

Growing poverty is an important variable that globally prevents the decline in the number of cases due to tuberculosis. Poverty has always been associated with tuberculosis.[140] A decline in the incidence of tuberculosis seen in the European countries in 19th century was parallel to the reduction of poverty. Economic downfall in Russia in the last decades has been linked to the increased incidence of tuberculosis in that country.[141] Along with HIV/AIDS and malaria, tuberculosis is implicated as one of the three major diseases associated with poverty.

Malnutrition and Immunosuppression

Immunosuppression and malnutrition form the basis for many, if not all, the factors to produce the varied effects of this disease. The population of patients whose host defences are compromised by the underlying diseases or by the medical treatments continue to increase; posing new and complex threats to the ongoing control measures. Both these factors play a pivotal role, not only in the reactivation of latent infection, but also in acquiring primary infection. Contributions of these variables in the development and progression of tuberculosis have already been described under the relevant headings.

Chronic Renal Failure

Chronic renal failure impairs immune function and is associated with an increased incidence of TB. Rates of tuberculosis are 10- to 25-fold amongst patients of renal failure on renal replacement therapy (hemodialysis or continuous ambulatory peritoneal dialysis), equating to incidence rates of approximately 250 per 1,00,000 per year.[142-145]

Ethnic and Genetic Factors

It has long been recognized that certain population appears to have a high degree of vulnerability to tuberculosis. Extreme susceptibility to the disease has been observed in Eskimo population in North America, Yanomami Indians in the Brazilian Amazon and black population in the United States.[146-148] Host genetic factors also influence disease expression, with reports from India suggesting a clear association between HLA-DR2 and increased risk of progression to advanced disease.[149] It has also been shown that DRB1*1501 allele correlates with advanced disease and treatment failure and that DRB1*1502 correlates with decreased risk.[150] A clue to the genetic basis of resistance was provided by the studies of Gros and colleagues who identified a strain of mice with exquisite vulnerability to overwhelming infection with certain bacteria and some strains of mycobacteria , particularly *Mycobacterium bovis*.[151,152] Eventually, the genetic basis of this susceptibility was mapped to a locus encoding a gene on murine chromosome 1, initially called *Bcg,* then renamed *Nramp1*, responsible for the production of a so-called natural resistance-associated macrophage protein.[152]

Several polymorphisms of the human *Nramp1* gene have been identified and population-based studies in several regions have been conducted, which have identified increased relative risk for moving from latent infection to active disease associated with certain polymorphisms.[153] However, the risk attributable to these polymorphisms is relatively small, and it is clear that *Nramp* alone explains only a portion of genetic susceptibility to tuberculosis. Several other genes and gene families, including those for vitamin D receptors and the components of IFN-γ–signalling pathways, have also been studied for their role in susceptibility to tuberculosis.[154-155] A recent study has concluded that a variation in the 3' untranslated region of the tumor necrosis factor receptor superfamily member 1B gene, which has been shown to be implicated in messenger ribonucleic acid destabilization, contributes to tuberculosis susceptibility.[156] These investigation clearly suggests that resistance or susceptibility to tuberculosis is a complex genetic trait and it is highly unlikely that there is a single dominant genetic factor involved.

In conclusion, the mere fact that more than a quarter of the world's population is infected with *M. tuberculosis* and the active disease remains a worldwide pandemic in spite of the availability of effective antitubercular drugs, bears testimony to the fact that risk factors of TB continue to pose a big challenge. The presence of a large number of these variables is an important determinant of the occurrence of TB, as well as of its clinical spectrum and course.

Mycobacteria: An Overview

Romica Latawa, Indu Verma

INTRODUCTION

Mycobacterium tuberculosis (*M. tb*) is a gram-positive, nonmotile acid-fast bacillus **(**retention of carbol fuchsin dye even after treatment with acidic alcohol due to the presence of waxy mycolipids in its cell wall), which occur in the form of pleomorphic non-sporulated rods.[1] It belongs to the actinomycetes group with a length of approximately 1–4 µm and diameter of 0.3–0.6 µm. In smears stained with carbol fuchsin and examined under light microscope, the tubercle bacilli typically appear as pink colored straight or slightly curved rods.[2] *M. tuberculosis*, like any other bacteria, has a life cycle consisting of lag, log, stationary and death phases. It is an obligate intracellular, slow growing aerobe that divides every 16–20 hours and has DNA with a high Guanine-Cytosine (GC)-content (60 to 70%).

Cell Wall Structure

Mycobacterium has an extremely uncommon cell wall structure; up to 60% of the mycobacterial cell wall is composed of lipids that consist basically of uncommonly long-chain fatty acids with 60 to 90 carbons, denominated as mycolic acids.[3] A far more distinctive feature is that mycolic acids are branched fatty acids that have a short and a long branch, with 22 to 24 and 40 to 64 carbons, respectively; they are covalently linked to the polysaccharide that composes the cell wall, the arabinogalactan, which in turn is attached to peptidoglycan by a phosphodiester link.[3] This unusually impermeable cell wall of mycobacterium is thought to be advantageous in withstanding weak disinfectants and surviving in a dry state for weeks,[2] in stressful conditions of osmotic shock or desiccation, as well as contributing to its considerable resistance to many drugs.[1]

Mycobacterial Groups

The most important of mycobacterial group is *Mycobacterium tuberculosis* complex (MTC), which includes *M. tb*, *M. leprae, M. bovis* and *M. africanum*. *M. tuberculosis* and *M. leprae* cause tuberculosis and leprosy, respectively, in humans. *M. bovis* causes tuberculosis in cattle and in humans. Some mycobacteria are saprophytes (i.e. they live on decaying organic matter), and others are obligate parasites. Most are found in the soil and water in a free-living form or in the diseased tissues of animals. The other group “atypical mycobacteria” that is different from typical MTC on the basis of their *in vitro* characteristics is the Nontuberculous Mycobacteria (NTM). In 1950s, it was divided into four categories on the basis of Runyon classification: Photochromogens, that produced pigment only when exposed to light, e.g. *M. kansasii, M. marinum*; Scotochromogens, produced pigment irrespective of light exposure, e.g. *M. scrofulaceum, M. xenopi*; Nonchromogens, that did not produce any pigment, e.g. MAC, *M. terrae* complex; and rapidly growing mycobacteria, e.g. *M. chelonae, M. fortuitum*.

Mycobacterium avium and *Mycobacterium intracellulare* are closely related and commonly grouped to form the *Mycobacterium avium* complex (MAC) that is implicated as a potential pathogen for both animals and humans. In patients with HIV infection and/or AIDS, opportunistic infections, caused by the atypical mycobacteria, include the *M. avium* complex, *M. kansasii*, *M. fortuitum* and *M. chelonae*, although these species are essentially saprophytic. *Mycobacterium avium,* however, is the most clinically significant of the environmental mycobacteria that opportunistically infects susceptible humans having systemic immunosuppression.[4]

Mycobacterial Identification

The identification of different mycobacterial species is based on their phenotypic characteristics such as the growth rate, colony morphology and pigmentation. It is possible to distinguish *M. tuberculosis* and *M. avium* using culture and a battery of biochemical tests, but these are complicated and time consuming. The biochemical tests, which are specific for *M. tb* are niacin reduction test, nitrate test and urease test. Niacin test is considered a confirmatory test for *M. tb* identification as nearly all strains of *M. tb* are unable to metabolize niacin that is produced during mycobacterial growth. This excess niacin is then secreted into the surrounding medium where it can be detected. On the other hand, tellurite reduction and catalase tests are given positive specifically by MAC species.

Route and Spread of Infection

After inhalation of infectious droplets from an infected individual, mycobacterium normally enters the host via mucosal surface of the lung rich in oxygen supply, which provides a suitable environment for this slow replicating pathogen. The infection is established in the alveolar spaces, where phagocytic cells take up the bacteria. Ingestion of bacteria includes a rapid inflammatory response, which results in the recognition of the pathogen by adaptive immune response and thus leads to the accumulation of a variety of immune cells followed by the formation of granuloma, characterized by a relatively small number of infected phagocytes surrounded by activated monocytes/macrophages and activated lymphocytes.[5]

The complex immune responses mounted against *Mycobacterium tuberculosis* are well defined at cellular level and involve both innate and adaptive immune responses. One of the most remarkable features of the nonsporulating *M. tuberculosis* is its ability to remain dormant within an individual for decades before reactivating into active tuberculosis.[6] Latent TB is a clinical syndrome caused by exposure to *M. tuberculosis*, followed by the establishment of infection and host's immune response to control bacillary growth, forcing it into a quiescent state in the infected tissue. It is a state of mycobacteria surviving in closed necrotic lesions, characterized by a reduction of bacterial metabolism, as a consequence of the action of cellular immune response, and which can, to a certain point, contain, but not eradicate the infection.

Mycobacterial Genome

Sequencing of *M. tuberculosis* H37Rv (a virulent laboratory strain) by Cole and co-workers in 1998 revealed it to possess 4,411,532 bp, the second largest microbial genome sequenced at that time.[7] Mycobacterial genome is comprised of approximately 4,000 genes and around 4% of the genome is composed of Insertion Sequences (IS) and phages. Specificity of these IS elements act as a fundamental tool for the identification of different mycobacterial species. For example, IS6110 is the IS that is most abundantly present in *Mycobacterium tuberculosis* whereas IS1110 and IS1245 are specific to *Mycobacterium avium*. The sequencing of mycobacterial genome has provided an invaluable insight into the biological functions of this organism. The most important fact about *M. tb* genome is that approximately 8% of the total genome is involved in encoding the enzymes of lipid metabolism that indicates the significance of lipids in *M. tb* life cycle. On contrary, the genome surprisingly encodes a number of lipolytic proteins that may be important in host pathogen interactions.

Another important finding of *M. tuberculosis* genome project was the identification of large novel gene families PE and PPE, which have a conserved N-terminal region with the characteristic motifs ProGlu and ProProGlu respectively. Another such class of novel mycobacterial proteins is PE proteins that belong to Polymorphic GC-Rich Sequence (PGRS) family that has glycine as half of its amino acid content. These genes are considered to be important as a source of genetic diversity in *M. tb.*

Mycobacterium pathogenicity is attributed to the various genes and the cellular components they encode, which are known as virulence factors and the most important of these are the transcription regulators. Among transcriptional regulatory proteins, there are 13 sigma factors (e.g. Sigma A, F, E, H, etc.) that confer the transcriptional specificity to RNA polymerases. They basically control the mycobacterial response to external stimuli and are induced after the exposure of the organism to various environmental stresses such as high temperatures, detergents etc.[8] Other regulatory proteins include two component response regulators (e.g. PhoP, PrrA, mprA) that are activated by the environmental signals and also serve as transducer of these signals. These genes constitute approximately 0.6% of the total mycobacterial genome.

In addition to these proteins, a number of genes have been identified in mycobacterial genome that encode for various cell surface components that are particularly unique to pathogenic mycobacteria and are speculated to be *M. tb* virulence factors. In this category, those genes are included that code for the proteins expected to be exposed to the environment in which *M. tb* grows, e.g. surrounding culture medium during *in vitro* conditions and mycophagosome under *in vivo* conditions. These proteins are either secreted proteins or the enzymes that have an important role in the synthesis of various cell surface components. The secreted proteins are also called as Culture Filtrate Proteins (CFPs) due to their release in the culture media in which *M. tb* is grown. There are ~ 200 CFPs and these proteins are considered to be an early target of host immune system for the generation of anti-mycobacterial immune responses. Due to these facts, live attenuated *M. tb* vaccines are considered to be better than heat killed bacilli. Some immunodominant culture filtrate proteins include Antigen 85 complex, ESAT6, CFP10, HspX, etc.

Genomic Analysis

Comparative genomic analysis has revealed the existence of several *M. tuberculosis*-specific regions that have been deleted from Bacillus Calmette-Guérin (BCG). The *in vitro* attenuation of BCG was accompanied by the loss of several major deleted regions, which presumably contained virulence factors that would not be primed by a BCG vaccination. These antigens may include important protective T-cell antigens and are thus attractive vaccine candidates to supplement BCG vaccination or for the T-cell based diagnostic assays such as Interferon Gamma Release Assays (IGRAs). In total these major deletions include 129 Open Reading Frames (ORFs), which are missing in some or all strains of BCG.[9,10] The RD1 region, responsible for the initial attenuation of BCG[9] contains eight ORFs and is present in all clinical isolates of *M. tuberculosis* and *M. bovis*. These genes play an important role in virulence, demonstrated by the attenuation of *M. bovis* and *M. tuberculosis* strains that carry knockout mutations in the RD1 region.[11-13] Four highly reactive T-cell antigens, ESAT-6, CFP-10, TB27.4 and TB37.6, are encoded by neighboring genes in this region.[14-17]

To sum up, considerable information is now available in the literature regarding the chemical structure and immunological properties of *M. tb* unique cell envelope. Further, decoding of *M. tb* genome has provided us a wealth of information that can be important for the understanding of the molecular basis of *M. tb* pathogencity. This in turn can be translated into the development of new drugs, diagnostic tests and vaccines to combat tuberculosis and for the development of novel control strategies for tuberculosis.

Immunology and Pathogenesis

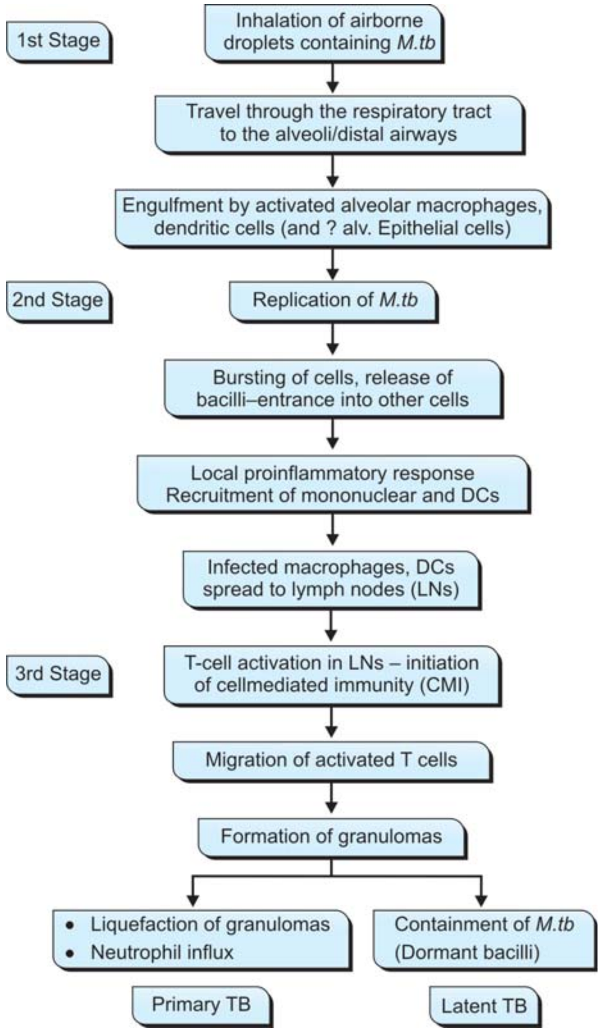
Krishna K Singh, Indu Verma

INTRODUCTION

Mycobacterium tuberculosis (*M. tb*), the causative agent of tuberculosis (TB) is one of the most successful human pathogens, which continues to kill more people than ever before worldwide. In approximately 5 to 10% of the individuals who get infected with *M. tb*, the bacteria continue to replicate, resulting into clinical TB. In the remaining 90 to 95% of the infected individuals, effective immune responses are elicited, which contain the bacteria in granulomas where they persist latently for several years. It is estimated that the one third of the world population is latently infected with *M. tb* and only 5 to 10% of these individuals develop TB some time in their lifetime when their immune system is compromised due to ageing, malnutrition, physical stress, immnuosupressive drugs and Human Immunodeficiency Virus (HIV) infection. Thus, it is clear that immune responses elicited in majority of *M. tb* infected individuals are sufficient for inhibiting the development of TB. This chapter is focused on providing the current understanding of the role of immune responses in pathogenesis of TB.

MYCOBACTERIUM TUBERCULOSIS INFECTION AND OVERVIEW OF IMMUNOPATHOGENESIS

Despite several recent advancements, the pathogenesis of TB is still not clearly defined. The current view of TB pathogenesis in human can still be pictured as a multiple-stage process, which was described over a decade ago using the rabbit model of TB.[1] Overall, it is a kind of tug of war between host immune system and tubercle bacillus (Fig. 39.1).



1st Stage
Inhalation of airborne droplets containing M.tb
Travel through the respiratory tract to the alveoli/distal airways
Engulfment by activated alveolar macrophages, dendritic cells (and ? alv. Epithelial cells)
2nd Stage
Replication of M.tb
Bursting of cells, release of bacilli–entrance into other cells
Local proinflammatory response Recruitment of mononuclear and DCs
Infected macrophages, DCs spread to lymph nodes (LNs)
3rd Stage
T-cell activation in LNs – initiation of cellmediated immunity (CMI)
Migration of activated T cells
Formation of granulomas
• Liquefaction of granulomas
• Neutrophil influx
Containment of M.tb (Dormant bacilli)
Primary TB
Latent TB

Fig. 39.1: Various stages in the pathogenesis of tuberculosis

The first stage starts with the inhalation of small airborne droplet (1–5 μm) containing *M. tb* expectorated by an individual with pulmonary or laryngeal tuberculosis while coughing, sneezing or talking.[2] These droplets can remain in the environment for several hours. Various factors that affect the likelihood and intensity of aerogenic transmission of *M. tb* from a TB index case to a contact person include (i) duration and intensity of the exposure; (ii) cough and sputum-related host factors; and (iii) virulence of *M. tb* strain.[3] The infectious droplets pass through the upper parts of the airways where the majority of bacilli are trapped in mucus and removed by cilia. The remaining droplets containing bacteria settle in the alveoli of distal airways where they are engulfed non-specifically by activated alveolar macrophages, Dendritic Cells (DCs) and probably by alveolar epithelial cells also.[4,5]

Being a successful human pathogen, *M. tb* has developed various strategies to avoid the intracellular killing mechanisms of host cells. Thus, the second stage begins with the replication of bacilli in alveolar macrophages, to some extent in DCs and possibly in alveolar epithelial cells. The bacilli multiply in these cells until they burst, the released bacilli are ingested by other alveolar macrophages. It is followed by a localized proinflammatory response, which directs the recruitment of mononuclear and DCs from neighboring blood vessels, providing fresh host cells for expanding the bacterial population and also induces alveolar macrophages to invade the lung epithelium.[6-9] The accumulation of these cells at the site of infection initiates the early lesion formation in the lung.[1,7,8] Simultaneously, the bacilli ingested macrophages and DCs disseminate to lymph nodes via the lymphatic system[2,7] or probably by the direct breaching of alveolar wall.[10]

The arrival of bacilli containing macrophages and DCs to the lymph nodes initiates the cell-mediated immunity (CMI), which is the beginning of the third stage of the pathogenesis. Recent studies have shown that T-cell activation starts in lymph nodes draining the lung and the development of CMI occurs between two to eight weeks postinfection in the majority of individuals.[2,11] The activated T-cells expand and migrate to the site of infection in the lung where they activate macrophages and induce the formation of granulomas. Initially, the granuloma is an amorphous mass of various cells, which becomes more organized and stratified structure with the development of acquired immune response.[6] In human, the granuloma is the hallmark of pulmonary TB, characterized by a central acellular eosinophilic region of caseous necrosis surrounded by the concentric layers of macrophages, large epitheloid cells, multinucleated giant langhans cells and lymphocytes.[12,13] The central necrotic core of the granuloma with sparse mycobacteria is surrounded by the two layers of cells.[13] The inner layer consists of mycobacteria containing CD68$^+$ Antigen Presenting Cells (APCs), epitheloid cells and giant langhans cells. This layer is also rich in CD4$^+$ T-cells and CD45RO$^+$ memory cells, but CD8$^+$ T-cells are rarely present.[13] The outer layer is found to contain mycobacteria infected APCs, numerous CD4$^+$ and CD8$^+$ T-cells and different types of B-cells (CD23$^+$ naïve, CD27$^+$ memory and plasma B-cells).[13]

Foamy macrophages (macrophages filled with lipid containing bodies) infected with mycobacteria have been demonstrated in the interface region flanking the necrotic core in the granulomas of TB patients.[14] It is suggested that these cells might act as a nutrient reservoir for persistent mycobacteria in the granuloma.[14] During the early phase of granuloma formation, the structure is highly vascularized. However, as granuloma matures, blood vessels start disappearing and a fibrous sheath of collagen and other extracellular matrix components form around macrophage rich layer leaving majority of lymphocyte outside.[15] At these "late" stages, the caseous portion of the granuloma becomes hypoxic; bacilli stop replicating and enter into a dormant phase.[16] Successful granuloma formation and maintenance leads to the containment of the pathogen.[12,17] The infected individuals at this stage show no overt sign of disease and categorized as individuals with latent TB.

In the majority of latently infected individuals, the bacilli remain dormant for their entire life and never cause TB. Unfortunately in some of these individuals, at the time when their immune system becomes weak, the tubercle bacilli out—compete the host immune response and start undergoing intracellular replication. This results into the extensive macrophage death and necrosis and the granuloma starts liquefying to form cavity, which permits the spill of numerous viable bacilli into airways.[12,15] Recent immunohistochemical analysis of the human tuberculous cavities showed that during liquefaction, the bacilli replicate rapidly in macrophages lining the surface of the cavities rather than in the extracellular acellular necrotic material, which was thought previously.[12,18]

In late-stage disease, neutrophil influx has also been implicated in the tissue damage and the dissemination of infectious bacteria into the airways in TB patients.[19] Despite evidence of T-cell responses in granulomatous layer of cavity to control bacillary growth, rapid replication of bacilli occurs in the cavity resulting huge load of bacilli in the respiratory tree.[18] This final stage of the TB pathogenesis completes with development of productive cough, which promotes the spread of viable bacilli in the aerosol droplets to other individuals. This process is an important step in the life cycle of *M. tb* for maintaining itself in human population.

IMMUNE RESPONSES TO TUBERCULOSIS

As described above, during the entire life cycle of the *M. tb* from the inhalation of a few bacteria in the lung to the generation of large number of bacilli in the airway by liquefaction of granuloma, there is a constant battle between *M. tb* and immune system. Although immune system is able to control infection in the majority of infected individuals, a small proportion of these individuals loose this battle and develop TB. Currently, the mechanism of immune defense against mycobacteria is not clearly known, however, our understanding has considerably increased due to elegant studies performed in the past decade. These studies have demonstrated that both innate and adaptive immune systems are involved in providing immunity against *M. tb* (Table 39.1). The following sections are aimed to describe current knowledge about innate and adaptive immunity to TB.

Innate Immunity

In general, innate immune system recognizes microbes immediately after infection by using receptors and induces secretion of a range of chemokines and cytokines, which direct the recruitment of various immune cells, including the phagocytic cells to the site of infection to kill the microbes. Although the mechanism of innate immunity during *M. tb* infection is poorly understood, the contribution of different components of innate immune system is discussed.

TABLE 39.1: Role of different immune responses in tuberculosis

A. Innate immunity
  i. Role of receptors
  ii. Role of macrophages and dendritic cells (DCs)
  iii. Role of Natural killer (NK) cells
  iv. Role of Neutrophils
B. Cytokines and chemokines bridging the innate and adaptive immunity
C. Adaptive immunity
  a. Cell-mediated immunity
    i. Role of $CD4^+$/$CD8^+$ T-cells
    ii. Role of regulatory T (T_{reg}) cells
    iii. Role of $\gamma\delta$ T-cells
    iv. Role of memory T (T_M) cells
    v. Role of unconventional T-cells
  b. Humoral immunity – Role of B-cell

Role of Receptors

Upon entry into the host lungs by aerosol inhalation, *M. tb* interacts with various receptors, such as the Pattern Recognition Receptors (PRRs), which include toll-like receptors (TLRs), Nucleotide-Binding and Oligomerization Domain (NOD)-like Receptors (NLRs) and dectin-1.[7,20] Other receptors involved in this interaction include Complement Receptor 3 (CR3), Mannose Receptor (MR), scavenger receptor, DC-Specific Intercellular-Adhesion-Molecule-3-Grabbing Non-integrin (DC-SIGN) on the surface of macrophages and DCs.

TLRs are transmembrane receptors present on macrophages, DCs, B-cells, specific types of T-cells, as well as on fibroblasts and epithelial cells.[21] The role of various TLRs in *M. tb* infection is not clearly understood, but it is likely that TLR2, TLR4 and TLR9 are involved in signaling innate immune responses against *M. tb* infection.[7] Several mycobacterial proteins, such as 19 kDa lipoprotein (LpqH), LprA, LprG, 38 kDa, PE-PGRS33, HSP65, HSP70, and lipids like Phosphatidyl-Myo-Inositol (PIM), lipomannan (LM), Mannose-Capped Lipoarabinomannan (ManLAM), Glycopeptidolipids (GPL) have been identified as ligands for TLR2 and TLR4.[7,22] The interaction of these mycobacterial ligands with TLR2 and/or TLR4 have been shown to induce the production of proinflammatory (TNF-α, IL-6, IL-12) and anti-inflammatory (IL-10) cytokines, DC maturation, cell apoptosis and mycobacterial killing.[7,22] TLR9 is found to recognize mycobacterial DNA and signals synthesis of proinflammatory cytokines.[7]

Activation of TLRs also leads to upregulated expression of the vitamin D receptor (VDR) and the vitamin D-1-hydroxylase genes resulting in to the conversion of provitamin D into the active form 1,25(OH)2D3. This leads to the induction of the antimicrobial peptides cathelicidin and β-defensin to kill intracellular mycobacteria.[23,24] In a recent study, when TLR2/4/9 triple-deficient mice and adaptor protein myeloid differentiation primary response protein 88 (MyD88) deficient mice were infected with *M. tb*, while growth of *M. tb* in the lung of TLR2/4/9 triple-deficient mice was observed to be similar to the wild type mice, bacterial load in MyD88 deficient mice was found significantly higher compared to wild type.[25] These results suggest that TLR 2, 4 and 9 are not critical for restricting *M. tb* growth, but MyD88, which is involved in TLRs signaling, plays an essential role in protection against TB.

Another transmembrane PRR; dectin-1 is found on macrophages and DCs and binds to β-glucan.[21] Although, dectin-1 plays an important role in antimicrobial response in fungal infections, involvement of dectin-1 in mycobacterial infection is not well studied[21] except that it is shown to be involved in eliciting proinflammatory response to *M. tb* infection.[26] It has also been demonstrated that NOD2, which belongs to NLRs family of cytosolic receptor proteins recognizes muramyl dipeptide and induces the production of proinflammatory cytokines following interaction with *M. tb*.[20] In addition, NOD2 and dectin-1 cooperate with TLR-2 during interaction with *M. tb* to activate NF-κB and induce proinammatory cytokines, including TNF-α, IL-1, IL-12, IL-18 and chemokines, which attract neutrophils, NK cells, T-cells, DCs and macrophages to the infection site.[20,27]

The interaction of receptors with *M. tb* results in not only the induction of proinflammatory cytokine response, but also serves as a mechanism for bacilli to avoid killing by innate immune cells. Amongst complement receptors, the phagocytosis of *M. tb* via CR3 has been found to prevent respiratory burst leading to phagosomal arrest of early endosomes and no inflammatory response.[7] Mannose receptor mediates phagocytosis by binding to ManLAM of *M. tb*, which results in the inhibition of phagosome-lysosome fusion leading to increased survival of *M. tb* in macrophages.[7] Number of host components, such as Surfactant Protein -A (SP-A) and -D (SP-D) also affect the uptake and survival of *M. tb* in macrophages.[7] Recent studies have shown that plasma membrane cholesterol is essential for the phagocytosis of *M. tb* by macrophages and it aids in preventing phagosome-lysosome fusion by mediating the phagosomal association with Tryptophan Aspartate-Containing Coat Protein (TACO), which avoid lysosomal degradation of *M. tb*.[28]

Role of Macrophages and Dendritic Cells (DCs)

The uptake of *M. tb* by alveolar macrophages represents the first step in the innate host defense against TB. Following mycobacterial infection, macrophages can differentiate either in IL-23-producing type 1 macrophages that promote Th1 immunity to mycobacteria or IL-10-producing type 2 macrophages that suppress immunity to myco-bacteria.[29] IL-10 producing type 2 macrophages can also induce $CD4^+$ T-cells to adopt regulatory T-cells (Treg) phenotype.[30] IFN-γ is key activating agent that triggers the antimycobacterial effects of macrophages.[31,32] A major effector mechanism responsible for the antimycobacterial activity of IFN-γ is the induction of nitric oxide and related reactive nitrogen intermediates by macrophages via the action of inducible form of nitric oxide synthase.[33,34] Along with IFN-α, TNF-α and IL-1α also stimulate the production of nitric oxide in macrophages. The precise mechanism(s) by which nitric oxide and other reactive nitrogen species antagonize *M. tb* is not known. It is suggested that it may involve the disruption of bacterial DNA, proteins, signaling, and/or induction of apoptosis of macrophages that harbor mycobacteria.

In spite of the potent bactericidal activity of macrophages, *M. tb is* able to survive and replicate in these cells by avoiding the killing mechanisms. It has been shown that *M. tb* survive inside macrophage by avoiding the fusion of phagosomes with lysosomes.[7,35] Retention of early endosomal markers by *M. tb* vacuole longer than normal maturing phagosomes suggested a defect in maturation of *M. tb* phagosome.[36] *M. tb* phagosomes are shown to be deficient in lysosomal hydrolases and Vesicular Proton-Adenosine Triphosphatase (v-ATPase) required for the acidification of phagosomes.[7,36] Also, *M. tb* phagosome fails to replace the small GTP-binding Rab family protein Rab5 with Rab7, which is a critical step during phagolysosome formation.[37] Furthermore, *M. tb* is observed to prevent the accumulation of Phosphatidylinositol 3-Phosphate (PI3P) on phagosome, which is a host membrane protein and essential for the biosynthesis of phagolysosome.[36]

Recently, LAM from *M. tb* has been demonstrated to inhibit phagosome maturation via blocking cytosolic Ca^{2+} increase, which is required for Ca^{2+}/calmodulin PI3 kinase responsible for PI3P production on phagosomes.[37,38] *M. tb* SapM, a eukaryotic-like acid phosphatase has been found to interfere with phagosome maturation by hydrolyzing PIP3 on phagosomal membrane.[39,40] The eukaryotic-like serine/threonine Protein Kinase G (PknG) of *M. tb* has also been demonstrated to inhibit phagosome-lysosome fusion.[41] Most recently, it is suggested that *M. tb* Protein Tyrosine Phosphatases (PtpA and PtpB) are involved in blocking the phgosome-lysosome fusion by interfering with host trafficking process.[40] Although, these studies provide a glimpse of the *M. tb* components involved in the blocking of phagosome-lysosome fusion, more research is needed to completely understand the role of *M. tb* molecules in its survival inside the macrophages.

Unlike macrophages, the interaction of DCs with *M. tb* is not well studied, but they have been shown to have a significant role in mounting protective immune responses against *M. tb* infection.[42] It has been shown that *M. tb* enters DCs via binding with DC-SIGN receptors.[5] Mycobacterial ManLAM has been found to be ligand for DC-SIGN and binding of ManLAM with DC-SIGN inhibits the maturation of DCs.[43] *In vivo*, it seems that similar to *M. tb* receptor, DC-SIGN is also utilized by HIV for its entry in these cells.[44] It is suggested that DC-SIGN might account for several pathological and immunological aspects of *M. tb* infection in subjects co-infected with HIV. Although *M. tb* is able to survive and persist in DCs, conflicting results have been obtained regarding its replication.[45,46]

Both macrophages and DCs can inhibit mycobacterial growth in nitric oxide dependent manner; however, *in vitro* studies have demonstrated that macrophages are more efficient in killing *M. tb* than DCs.[46] Similar to macrophages, mycobacterial vacuoles in infected DCs are also known to lack acidification and fusion with lysosomes, which suggest similar mechanism for survival of *M. tb* in DCs.[45] However, in contrast to macrophages, the finding of impaired communication between *M. tb* phagosomes and host recycling and biosynthetic pathways leading to the absence of essential nutrients needed for *M. tb* survival in the phagosomes of infected DCs indicates the different mechanism of survival and persistence of *M. tb* in DCs.[45]

Role of Natural Killer (NK) Cells

Natural killer cells are one of the major components of innate immune system and provide the first line of defense against infection.[47] The recognition of the target cells by NK cells is performed with a variety of cell surface activating receptors (NKp46, NKp44, CD16 and NKG2D) and inhibitory receptors (killer immunoglobulin-like receptors; KIRs and the NKG2A:CD94 dimer), which regulate the cytolytic activities of these cells.[47] In addition to cytotoxic activity, NK cells have also been found to be a potent early source of cytokines particularly IFN-γ, IL-5, IL-13 and IL-10.[47] Role of human NK cells in protection against *M. tb* infection is demonstrated by *in vitro* studies, which showed that NK cells can directly lead to lysis or apoptosis of *M. tb* infected monocytes and macrophages.[20] A recent study showed that NK cells restrict the growth of *M. tb* in macrophages via production of IL-22, which increases the phagosome-lysosome fusion.[48] NK cells can also regulate the expansion and cytotoxicity of $CD8^+$ T-cells for lysis of *M. tb* infected monocytes, which depend on the production of IFN-γ by NK cells, direct contact of NK cells with monocytes and secretion of IL-12, IL-15 and IL-18 by monocytes.[47]

Role of Neutrophils

The influx of Polymorphonuclear Neutrophils (PMNs) to the lung is one of the first events in the pathogenesis of pulmonary tuberculosis, which play a significant role in the acute phase of the disease.[49] In addition, protective role of neutrophils in systemic *M. tb* infection of mice has been demonstrated.[50] Moreover, studies with human neutrophils suggest that these cells restrict the growth of *M. tb* and secrete several cytokines and chemokines on interaction with *M. tb*.[20] The risk of development of TB is inversely associated with the neutrophil count in the blood from contacts of TB patients further supporting the protective role of neutrophils in TB.[51] The fact that IL-17 is important in the early phase of host defense against TB by attracting the neutrophils at the site of infection further confirms the role of these cells in antimycobacterial immunity.[20] However, massive production of IL18, another neutrophil attracting chemokine in the lung of active TB patients indicates a pathological rather than protective role of neutrophils at late stages of the disease.[20] It is also observed that the ingestion of apoptotic neutrophils by macrophages enhances *M. tb* killing.[20,52] Thus, majority of studies indicate that neutrophils contribute to protective immunity against TB during early stages.

Cytokines and Chemokines Bridging the Innate and Adaptive Immunity

The majority of immunocompetent individuals control mycobacterial infection efficiently. This is mainly owing to an efficient coordination of both innate and adaptive immune responses by the cytokine and chemokine network. The control of *M. tb* infection depends on the appropriate development of inflammatory responses because improper responses can cause chronic infection and associated pathology.

Infected macrophages and dendritic cells produce Interleukin-12 (IL-12), the crucial cytokine in controlling early *M. tb* infection.[53,54] IL-12 induces the secretion of IFN-γ and down modulation of IL-10 and IL-4 that results in the differentiation of naïve T-cells to Th1 cells. IL-12 therefore provides an important link between innate and adaptive immune system.[54] Increased susceptibility to *M. tb* infection observed in IL-12 deficient mice indicates its role in protective immunity to TB.[55]

IFN-γ, secreted from activated T-cells and NK cells can further activate macrophages resulting into phagosomal maturation and production of antimicrobial reactive nitrogen intermediates and reactive oxygen intermediates to promote bacterial killing.[56,57] IFN-γ production is controlled by cytokines released by Antigen Presenting Cells (APCs) mainly IL-12 and IL-18.[58] IFN-γ signaling pathways can also induce autophagy in macrophages that further increases their bactericidal capacity.[59,60] Role of IFN-γ in human TB has been demonstrated by studies which show that individuals defective in either IFN-γ or IFN-γ receptor genes are susceptible to mycobacterial infections.[55] Besides IFN-γ, TNF-α, a proinflammatory cytokine secreted by macrophages, DCs and T-cells also plays an important role in killing intracellular *M. tb* through reactive nitrogen intermediates together with IFN-γ and are involved in granuloma formation.[53,61] The role of TNF-α in protective immunity against *M. tb* in human is suggested by studies showing increased susceptibility to develop TB in Crohn's disease and rheumatoid arthritis patients using anti-TNF-α antibodies.[55] Furthermore, variations in TNF-α receptor 1 (*TNFR1*) gene are found to be associated with TNF-α production and progression of active TB.[55]

IL-10, an anti-inflammatory cytokine produced by macrophages, DCs, B-cells and T-cells plays an important regulatory role in bacterial and viral infections by the inhibiting synthesis of proinflammatory cytokines like IFN-γ, TNF-α and IL-12.[55,62] In *in vitro* studies, IL-10 is shown to be upregulated in TB and inhibition of IL-10 has been shown to partially restore the suppression of T-cell proliferation.[55] In anergic TB patients, increased production of IL-10 also suggests its role in effective suppression of host immune response.[7] Polymorphisms in the promoter region of IL-10 are found to be associated with altered IL-10 level and susceptibilities to TB in human, however, inconsistent results of some studies raises question on role of IL-10 promoter polymorphism in TB susceptibilities.[55] IL-4 is another anti-inflammatory cytokine that has been implicated in various intracellular infections including *M. tb* for its harmful effects by suppressing IFN-γ production and macrophage activation.[62] In human, progressive TB, mainly in developing countries is found to be associated with increased IL-4 expression.[53,62,63]

Another anti-inflammatory cytokine that is implicated in suppressing protective immunity to *M. tb* is Transforming Growth Factor (TGF)-β.[64] Production of TGF-β by monocytes and DCs is induced by mycobacterial components specifically by ManLAM.[62,64] An increased production of TGF-β is observed in blood mononuclear cells and lung lesion of TB patients.[64] *In vitro* studies showed that suppressive effect of TGF-β on mononuclear cells from TB patients and *M. tb* infected macrophages is neutralized by its natural inhibitors.[62] TGF-β is also found to promote production and deposition of macrophage collagenases and collagen matrix suggesting its role in tissue damage and fibrosis during TB.[62] Inhibition of IFN-γ induced NOS2 production is shown to be responsible for deactivation of macrophages by TGF-β.[53] Also, TGF-β induces secretion of another anti-inflammatory cytokine IL-10 and both the cytokines have been observed to act in synergy for suppression of IFN-γ production.[62]

In addition to above mentioned cytokines, several investigators have shown that *M. tb* or its components induce chemokines from monocytes, macrophages, multinucleated giant cells, DCs, granulocytes, etc.[7,65,66] Evidence for *in vivo* production of chemokines in humans during *M. tb* infection is provided by studies showing the increased levels of CCL2, CCL5, CCL7, CCL12, CXCL8 and CXCL10 in Bronchoalveolar Lavage (BAL) fluid from TB patients.[66] Recently, expression of CXCL8 by mononuclear cells and fibroblasts in human tuberculous granuloma has also been observed.[65] *In vitro* studies have also demonstrated the influence of chemokines on intracellular growth of *M. tb*.[65] Neutralization of CCL4 and CCL5 is found to enhance the growth of mycobacteria in alveolar macrophages. Also, growth of *M. tb* is significantly reduced in macrophages stimulated with CXCL7. Furthermore, CXCL8 has been found to enhance the killing of mycobacteria by human granulocytes.

Various *in vitro* and *in vivo* studies suggest that cytokine TNF-α regulate the expression of chemokines during *M. tb* infection.[65,66] Neutralization of TNF-α production by LAM stimulated PBMCs and *M. tb* infected murine macrophages alter the secretion of various chemokines.[65,66] Expression of chemokine receptors CCR2 and CCR5 has also shown to be affected by TNF-α. Since, TNF-α is shown to play a crucial role in granuloma formation, whether chemokines are also involved in granuloma formation is not known.

Adaptive Immunity

Although, *M. tb* infection elicits both humoral and cell-mediated immune responses, due to intracellular residence of *M. tb*, it is well accepted that only cell-mediate immunity provides protection against TB.[53,67] However, in recent years it has been shown that humoral immune responses also play important role in protection to TB.[68,69]

Cell-Mediated Immunity

The T-cells which comprise of $CD4^+$ T Helper Cells (Th), $CD8^+$ Cytotoxic T-cells (CTLs), γδ T-cells, regulatory T-cells (T_{reg} cells), memory T-cells and unconventional CD1 restricted T-cells play main role in providing cell-mediated immunity. $CD4^+$ Th cells can be differentiated into Th1, Th2, Th17 and Treg cells. The Th1 cells produce cytokines, notably IFN-γ, TNF-α, IL-2, lymphotoxin etc., which further prompt the stimulation of Th1 cells, CTL, and macrophages maturation and activation. The cytokines, such as IL-12, IL-18 and costimulatory molecules have been found to facilitate the differentiation of $CD4^+$ T-cells into Th1 type.[56] The Th2 cells produce B cell-stimulation factors, such as IL-4, IL-5, IL-10 and IL-13, which promote antibody production, but suppress the Th1 type immune response. IL-4, IL-5 and IL-13 induce Th2 cell development. The Th17 cells produce unique cytokines IL-17, IL-17F, IL-21 and IL-22, which stimulate defensin production and recruit neutrophils and monocytes to the site of inflammation, and are involved in the early phase of host defense. IL-23, IL-6, IL-21 and low concentration of TGF-β could induce Th17 differentiation. $CD4^+CD25^+FoxP3^+$ Treg cells can affect the differentiation of Th1, Th2 and Th17 subsets by releasing TGF-β and IL-10.

Role of $CD4^+$/$CD8^+$ T-cells: The direct evidence for the involvement of $CD4^+$ T-cells in protective immunity against *M. tb* infection has been provided by several murine studies using $CD4^+$ T-cells depletion or adoptive transfer or genetically deficient mice.[53] In human, the protective role of $CD4^+$ T-cells during *M. tb* infection has been suggested by enhanced occurrence of both primary and reactivated TB in HIV-infected individuals showing loss of these cells.[53,67] Although, the mechanism of protection by $CD4^+$ T-cells is not clear, so far studies suggest that during *M. tb* infection, $CD4^+$ T-cells of Th1 type activate macrophages primarily through IFN-γ production, which results in the induction of enzymes Inducible Nitric Oxide Synthase or Nitric Oxide Synthase 2 (iNOS or NOS2) and phagocyte oxidase (NOX2/gp91^{phox}) to produce mycobactericidal Reactive Nitrogen Intermediates (RNI) and Reactive Oxygen Intermediates (ROI) respectively.[56,70] Although, these studies suggested that $CD4^+$ T-cells controls *M. tb* infection via IFN-γ production, other antimycobacterial mechanisms suggested for these cells include apoptosis of infected macrophages, release of ATP and Lymphotoxin α_3 ($LT\alpha_3$) or TNF-β for control of *M. tb* infection.[56,71]

Despite potent abilities of $CD4^+$ T-cells to control *M. tb* infection, existence of persistent infection in the majority of *M. tb* infected individuals suggests that these cells are ineffective in eliminating the *M. tb* infection. Although, reasons are not clearly known, it has been shown that *M. tb* infection reduces the antigen presentation by macrophages to $CD4^+$ T-cells by the down regulation of surface expression of MHC class II molecules.[53] Moreover, delayed appearance of *M. tb* specific $CD4^+$ T-cells during *M. tb* infection compared to infection caused by other pulmonary pathogens can also contribute to the inabilities of these cells to clear infection.[72]

M. tb infection of mice with either β2-microglobulin or Transporter Associated with Antigen Processing (TAP) gene disruption, which results in the lack of both MHC class I (class Ia- and class Ib) molecules and $CD8^+$ T-cells has demonstrated that $CD8^+$ T-cells are also required for control of *M. tb* infection.[53,72,73] Since *M. tb* resides in phagosomes, it is still unclear how *M. tb* antigens gain access to the MHC class I processing system. It has been suggested that *M. tb* perforates the membrane of phagosome by which its antigens translocate to MHC class I pathway.[53,56] However, other studies have provided evidence against the translocation of molecules from phagosomes to cytoplasm.[56] Although, the main function of the $CD8^+$ T-cells is the lysis of infected cells, it is also most likely that IFN-γ from $CD8^+$ T-cells activates macrophages and participates in the killing of *M. tb* as described above for $CD4^+$ T-cells. However, unlike $CD4^+$ T-cells, very low spontaneous IFN-γ production by $CD8^+$ T-cells is observed.[53] The $CD8^+$ T-cells can lyse the infected cells by using perforin and granulysin or Fas/FasL pathway.[53] Perforin forms pore and granulysin is required to kill the intracellular organism.[56] It has also been suggested that the lysis of infected cells by $CD8^+$ T-cells promotes the control of *M. tb* infection by the release of *M. tb* from incapacitated cells and their subsequent phagocytosis by activated macrophages.[56]

Role of regulatory T (T_{reg}) cells: T_{reg} cells express CD4, CD25 and Foxp3 and produce IL-10, TGF-β and IFN-γ.[75,76,82] In addition to $CD4^+CD25^+FoxP3^+$ T_{reg} cell subsets, $CD8^+$ T_{reg} cells inhibiting the T-cell proliferation and cytokine production are also described.[74] IL-2 and high concentration of TGF-β could induce T_{reg} differentiation[75,76] whereas IL-6 inhibits the generation of T_{reg} cells. T_{reg} cells are found to suppress the proliferation and function of $CD4^+CD25^-$ cells and inhibit the production of IFN-γ by secreting IL-10 and TGF-β.[77,78] During *M. tb* infection in mice, T_{reg} cells proliferate and accumulate at the site of infection and prevent efficient clearance of infection.[78]

Recent study also showed that TB patients have more T$_{reg}$ cells than healthy tuberculin responders and these cells inhibit BCG induced IFN-γ production by CD4$^+$ T–cells.[78,79] It has been observed that IFN-γ production by *M. tb* stimulated PBMCs is increased by depleting T$_{reg}$ cells.[78] Furthermore, expansion of T$_{reg}$ cells in response to *M. tb* infection is shown to be dependent on ManLAM and production of prostaglandin E2 by monocytes.[78] So far studies suggest that *M. tb* infection promotes the expansion of T$_{reg}$ cells that are able to suppress the protective immune responses developed against its own infection.

Role of γδ T-cells: During mycobacterial infection, γδ T-cell are rapidly recruited to lung, secrete IFN-γ and kill *M. tb* infected cells.[80,81] In humans, γδ T-cells recognize mycobacterial nonpeptidic phosphoantigens without any requirement for MHC molecules leading to the secretion of Th1 cytokines primarily IFN-γ and killing of *M. tb* infected cells.[80] The occurrence of increase size of granuloma and enhanced numbers of neutrophils in granuloma of *M. tb* infected γδ TCR-KO mice suggested that γδ T-cells are involved in the regulation of granuloma formation.[81] The involvement of γδ T-cells in providing protection against *M. tb* infection in human has been demonstrated by studies, which showed decreased number of Vγ9Vδ2 T-cells in the blood and lung of pulmonary TB patients, as well as diminished ability of Vγ9Vδ2 T-cells from TB patients to expand in response to *M. tb* or its antigens.[81] Together these studies suggest that γδ T-cells contribute to protective immunity against *M. tb* infection.

Role of memory T (T$_M$) cells: Although, role of T$_M$ cells in providing protection against *M. tb* infection is poorly defined, persistence of latent *M. tb* infection in majority of infected individuals suggest the involvement of these cells in controlling *M. tb* infection during latency. In humans, there are two types of T$_M$ cells; Effector memory T (T$_{EM}$) cells with CCR7^{lo}, CD62L^{lo}, CD69^{hi} and central memory T (T$_{CM}$) cells with CCR7^{hi}, CD62L^{hi}, CD69^{lo}[82]. *M. tb* infection in mice induces antigen specific T$_M$ cells; however, these memory responses provide only short-term protection.[67,72] Similarly, occurrence of *M. tb* reinfection in cured TB patients suggests that either no T$_M$ cells are induced or these cells are unable to provide protection. It has been proposed that efficient activation of effector T-cells for long time by persistent antigens can exhaust memory and cause no memory in extreme cases like in TB patients.[82] Recently, vaccination with BCG and MVA85A has been shown to induce long lasting poly-functional *M. tb* specific CD4$^+$ T$_M$ cells.[83]

Role of unconventional T-cells: In addition to MHC class I restricted CD8$^+$ T-cells, presence of non-classically restricted CD8$^+$ T-cells have also been observed during *M. tb* infection in humans.[53,56] Group I CD 1 molecules, which are structurally similar to MHC class I molecules have been found to present several lipids and glycolipid antigens of mycobacterial cell wall to non-classically restricted CD8$^+$ T-cells resulting into release of IFN-γ and expression of cytolytic activity.[53,56] Group I CD1a and CD1c can easily have access to mycobacterial antigens in phagosomes whereas group I CD1b molecules can primarily interact with those mycobacterial antigens that are shed inside the phagosomes and enter into late endosomes/lysosomes.[53,56] As group1 CD1 molecules are primarily found on DCs and almost absent on macrophages, the CD1 presentation therefore requires transfer of mycobacterial antigens from infected macrophages to bystander DCs.[56]

The natural killer T (NKT) cells are also unconventional T-cells that are group 2 CD1d restricted and stimulated by glycolipid antigens of mycobacterial cell-wall. *In vitro* studies showed that human activated NKT cells express granulysin and can kill the *M. tb*.[84] Another non-classical antigen presenting molecules H2-M3, a type of murine MHC class Ib molecules have been reported in mouse TB model and shown to present N-formylated peptides to CD8$^+$ T-cells.[53,56] The CD8$^+$ and CD4$^-$8$^-$ T-cells specific for mycobacterial N-formylated peptides are shown to produce IFN-γ and lyse *M. tb* infected macrophages.[53] Since homologues of H2-M3 molecules in humans are not identified, their role in human TB is not known.[56] However, CD8$^+$ T-cells restricted by non-classical molecules, but not CD1 restricted have been found in *M. tb* infected humans.[53]

Humoral Immunity

Historically, it is accepted that B cells play no significant role in providing protection against *M. tb* infection.[68,69,85,86] Although, studies of *M. tb* infection in B-cell-deficient mice have yielded variable results, recent data from *M. tb* infected B-cell-deficient mice and polymeric Ig receptor knockout mice deficient in secretory IgA have convincingly demonstrated a role of B cells and antibodies in protection against *M. tb* infection.[68,69] Moreover, protection observed by the administration of Intravenous Immunoglobulin (IVIg) against *M. tb* infection in mice and by passive serum therapy with anti-*M. tb* polyclonal antibodies to reactivation of TB in SCID mice further support the role of humoral components in host defense to TB.[68,69]

Monoclonal antibodies against several mycobacterial antigens, such as arabinomannan, LAM, 16-kDa α-crystallin, Heparin-Binding Hemagglutinin (HBHA) and MPB83 have been demonstrated to provide protection against TB in mice.[68,86] Following *M. tb* infection, B cells have also been found to influence the T-cell activation by regulating antigen presentation, as well as the modulation of cytokine profile thereby influencing the disease outcome.[69,87] Interestingly, a *M. tb* arabinomannan-Ag85B conjugated vaccine that induce both humoral and cellular immune responses has been observed to provide protection against *M. tb* infection in mice, rabbits and guinea pigs similar to BCG.[68,69]

Although, in humans, evidence for the role of B cells in immunity against *M. tb* infection is not available, presence of follicle-like B cell aggregates in the periphery of granuloma in the lung of TB patients suggest their role for maintaining the granuloma during *M. tb* infection.[13,69] The demonstration of significantly enhanced internalization and growth inhibition of BCG by neutrophil and monocyte/macrophages in the presence of serum from BCG vaccinated individuals and reversal of these effects by the depletion of IgG from serum suggest the involvement of anti-mycobacterial antibodies in protection against *M. tb* infection in humans.[68] Together, studies conducted in recent years support the role of humoral immune responses in defense against *M. tb* infection.

CONCLUSION

A complex interaction of multiple cell types of host immune system is important for optimal immunity against mycobacteria. The cross talk between *M. tb* and the host immune system determines the outcome of infection. After uptake of *M. tb* in alveolar macrophages and possibly other cells too, if infection is established, a focal nonspecific inflammatory response regulated by a network of proinflammatory and anti-inflammatory cytokines and chemokines derived from macrophages or DCs, NK cells and T-cells is elicited. This initial response determines the fate of infection either leading to local outgrowth of *M. tb* (sometimes dissemination) or containment of infection. At many stages in the host response, *M. tb* has developed mechanisms to circumvent or antagonize protective immunity. A clear picture of the network of host immune responses to this pathogen is essential to the design and implementation of effective vaccines and treatment strategies for tuberculosis. The combination of studies in animal models and human subjects, as well as technical advances in genetic manipulation of the organism, will help in enhancing our understanding of this immensely successful pathogen in the future.

Pulmonary Tuberculosis: Clinical Features and Diagnosis

S Kashyap, Malay Sarkar

INTRODUCTION

The clinical features of tuberculosis (TB) depend upon the site and the type of involvement. They are rarely diagnostic. Nonetheless, diagnosis in most of the patients is first suspected on the basis of clinical symptoms and signs. The primary site of implantation of bacilli in the lung parenchyma is called Ghon focus, which, together with the draining lymphatics and enlarged draining lymph nodes constitute the primary complex, also known as the Ranke or Ghon complex. In an immunocompetent host, development of specific immunity is usually able to arrest the bacillary proliferation within the primary lesion with little or no signs of illness, the initial lesion eventually resolves or calcifies. These healed lesions may contain dormant and viable bacilli, maintaining continuous hypersensitivity to tuberculous antigen, producing a state of latent TB infection. In a minority of infected individuals (10%), the disease progresses during the initial weeks or months after infection, and the patient develops the typical symptoms of progressive primary TB. In patients with little or no host response and overwhelming infection, disseminated/miliary TB may develop.

POST PRIMARY PULMONARY TUBERCULOSIS

Most common cause of post primary TB is the endogenous reactivation of dormant bacilli lying in residual foci. Coinfection with HIV is the strongest known risk factor for progression from latent infection to active TB.[1] Other known risk factors are malnutrition, drug and alcohol abuse, coexistent medical conditions, corticosteroid or other immunosuppressive and biological therapies.[1]

Exogenous reinfection can also be responsible for post primary TB, although less frequently. In endemic countries, using molecular genotyping methods, it has been demonstrated that reinfection with novel *Mycobacterium tuberculosis* strains may occur in 40% of relapsing cases of TB.[2] Reactivation can occur at any site; however, lung is the most common site of reactivation.[3] Post primary disease differs from primary TB in its preferential apical localization, a strong immune response, marked presence of caseation necrosis and cavities.[4] Traditionally, primary and post primary TB are described in children and adults respectively. Due to the presence of large number of immunocompromised patients and aging populations, atypical and “mixed” radioclinical patterns are frequently observed in adults, with the consequent fading of the age-related distinction between primary and post primary TB.

SYMPTOMS AND SIGNS

Pulmonary Tuberculosis (PTB) is a disease with protean manifestations, often associated with nonspecific constitutional and specific respiratory signs and symptoms. Constitutional symptoms include tiredness, malaise, weight loss, fever, night sweats, anorexia and headache. They are generally attributed to the release of various cytokines in the systemic circulation. Symptoms are minimal or absent until the disease is in an advanced stage. Complete absence of symptoms has been reported in 4.9% of active adult PTB cases, majority of patients are from countries with endemic TB.[5,6] Most patients develop symptoms insidiously; although, acute manifestations have been also reported.

Fever

Fever is an inconsistent symptom in pulmonary tuberculosis. Cowie et al.[7] reported fever in only 40% of 300 admitted patients. Similarly, Wang et al.[8] in a recent study reported fever in 33.3 and 15.4% of sputum positive and sputum negative pulmonary tuberculosis cases respectively. Absence of fever does not exclude the diagnosis of tuberculosis. Fever in pulmonary TB historically has been described by the typical evening rise of temperature. The evening spike of fever may be due to increase in the bacillary multiplication related to the diurnal pattern of adrenal gland steroid release. However, in miliary tuberculosis, fever can have morning spikes.[9] The other two conditions associated with morning temperature elevations are typhoid fever and periarteritis nodosa.[10] Initially, fever in PTB is of low grade, but it becomes high grade with the progression of disease. Tuberculosis is also an important cause of Fever of Unknown Origin (FUO) in several studies.[11,12] In a combined (prospective and retrospective) study of 150 cases of FUO, infections, particularly tuberculosis, were the most common (50%) cause.[12] Extrapulmonary tuberculosis is more common in such a situation.

Cough

Cough is the most predominant symptom in tuberculosis.[13] In the initial stages, cough is dry, but subsequently there occurs the production of mucoid or mucopurulent sputum, generally in small amounts. Sometimes, sputum may also be streaked with blood. At the onset, it is more in the early morning; with progressions of disease, it becomes persistent throughout day and night. Cough is less frequent in tubercular pleural effusion. A typical harsh, barking cough is often present in endobronchial TB, which responds to steroids and antituberculosis treatment, has poor response to antitussive medication.[14] As per ACCP guidelines, in the high prevalence areas of tuberculosis, chronic cough should be defined as cough of two to three weeks duration similar to that recommended by the World Health Organization (WHO).[15]

Hemoptysis

Hemoptysis is usually mild in TB, but occasionally it can be massive. When massive, it is mostly of bronchial artery or nonpulmonary systemic artery origin. Rarely, hemoptysis can also be the presenting symptom. Both active and inactive tuberculosis can produce hemoptysis. Tuberculosis is the most common cause of hemoptysis in endemic countries.[16] It was reported in 79.2% of 476 admitted patients of a chest department.[17] Similarly, in another report, approximately one-third of the patients of tuberculosis had hemoptysis of various grade at different stages of their disease.[18] However, the incidence of significant hemoptysis was 8% and fatal hemoptysis was reported in 1 to 5% cases.[18]

There are several mechanisms, which can cause hemoptysis in pulmonary tuberculosis (Table 40.1). Usually, massive bleeding is seen in inactive TB with cavitary and bronchiectatic sequelae. Bleeding occurs less commonly in patients of active cavitary disease with associated granulomatous vasculitis, since vascular thrombosis within necrotic areas causes the obliteration of pulmonary vessels.[19] However, it can be seen in active tuberculosis if adequate chemotherapy is not given and radiograph shows thick walled cavities.[20] After achieving cure, if the patient complains of recurrent hemoptysis, evaluation for bronchiectasis and/or mycetoma should be done.

Pulmonary mycetoma is the fungal colonization, mainly by aspergillus species, in a preexisting pulmonary cavity and without the evidence of invasion into the surrounding structures. Mycetomas have also been reported in other pulmonary conditions such as sarcoidosis, bronchiectasis, lung abscess, neoplasms, pulmonary infarcts, nontuberculous mycobacteria and various mycoses.[21-24] Severe hemoptysis may occur in up to one-third of the cases of mycetoma.[23] In HIV-infected patient with pulmonary mycetoma, significant hemoptysis is less likely observed as compared to immunocompetent patient, but these patients have a high risk of disease progression to more invasive disease.[24] Rasmussen's aneurysm is a rare complication of cavitary pulmonary tuberculosis caused by granulomatous weakening of a pulmonary arterial wall. It can present as the repeated episodes of minor hemoptysis or occasionally as major hemoptysis. Incidence of Rasmussen's aneurysm is 4% in patients with advanced cavitary disease.

TABLE 40.1: Mechanisms of hemoptysis in tuberculosis

- Necrosis of pulmonary venules and capillaries in early stages
- Rupture of *Rasmussen's aneurysm*
- Post-tubercular bronchiectasis
- Mycetoma in tubercular cavity
- Broncholiths
- Scar carcinoma–very rarely

Breathlessness

Breathlessness, which is a late symptom in pulmonary TB may result from extensive pulmonary involvement, bronchial obstruction, pneumothorax and pleural effusion. Rarely, patients with miliary TB or TB bronchopneumonia may present with the symptoms of respiratory failure. The incidence of respiratory failure secondary to pulmonary TB is 1.5 to 1.9%.[25-27] Diagnosis of TB is more likely delayed or missed in patients presenting with acute respiratory failure.[28] Destroyed lung due to tuberculosis is also a common cause of respiratory failure in endemic area.[29] The prognosis of TB presenting with respiratory failure is dismal with hospital mortality of 60%.[30]

Chest Pain

Involvement of pleural surface can cause pleuritic chest pain. Pain is referred to ipsilateral shoulder in diaphragmatic pleurisy and to upper abdomen in costal pleural involvement. Pneumothorax due to tuberculosis can also cause acute pleuritic chest pain. Sometimes, chest pain can be dull and poorly localized. Chest pain is an early and relatively frequent symptom and it disappears within two or three weeks after effective treatment is started.

Hoarseness

The most common cause of hoarseness of voice in pulmonary TB is due to the associated laryngeal tuberculosis. Rarely, inflamed TB nodes or the retraction of left upper lobe bronchus by cicatrization atelectasis can cause recurrent laryngeal nerve palsy and hoarseness of voice.[31]

In TB endemic countries, *M. tuberculosis* can have Community-Acquired Pneumonia (CAP) like presentation. Empirical therapy with fluoroquinolones in this condition, misdiagnosed as acute bacterial pneumonia, can suppress the early symptoms of TB and often delay the diagnosis of TB. Therefore, in endemic area for TB, fluoroquinolones should be judiciously used. In a multivariate analysis involving patients presenting with CAP like manifestations, features, such as the longer duration of symptoms (more than two weeks before hospital admission), history of night sweats, upper lobe involvement, cavitary infiltrates, lower total white blood cell count and lymphopenia, have been reported as more predictive of pulmonary TB.[32]

Primary TB in children is mostly asymptomatic and recognized solely through contact investigation. Some children may experience a symptomatic pneumonia like presentation. Progressive primary tuberculosis patients may present with cough, hemoptysis and weight loss. Because of smaller diameter airways, younger children are more prone to airway compression.[33]

TUBERCULOSIS IN THE ELDERLY

The elderly population is particularly susceptible to TB because of the age induced decline in cell mediated immunity.[34] More specifically, impairment of helper T-lymphocyte functions and subsequently defects in secretion and response to different cytokines are particularly important in increasing the susceptibility of TB in elderly subjects.[35] Elderly individuals are also more likely to suffer from various immunosuppressive conditions. There are several characteristics features of TB in the elderly.[36] After exposure, elderly subjects are more likely to become infected with *M. tuberculosis* than younger subjects, they also develop tuberculous diseases more easily after contracting infection. Mortality from TB is also high in this population.

Delayed diagnosis is not uncommon as the clinico-radiological presentations of TB are often atypical in the elderly.[37] Some patients may present with only non-pulmonary symptoms such as unexplained weight loss, weakness or change in cognitive status.[38] Classical symptoms, such as night sweats, fever and hemoptysis, are less frequently observed in the elderly.[5] Fever is infrequent because of age associated decrease in pyrogenic response. There is decreased responsiveness of the hypothalamic thermoregulatory center to prostaglandin E2 (released by interleukin-1) and an increased sensitivity to natural occurring antipyretics such as alfa melanocyte stimulating hormone.[39] Cavitation is less common in elderly age group, which can explain the lower frequency of hemoptysis. Potential of adverse drug reactions is also high in elderly subjects.

MILIARY TB

Miliary tuberculosis contributes 1 to 2% of all cases of tuberculosis and about 8% of all the forms of extrapulmonary tuberculosis in the immunocompetent individuals.[40] However, it is more common in immunosuppressed individuals. Clinical manifestations are nonspecific and the typical chest radiographic finding of miliary nodules may not be apparent till late in the course of the disease. Atypical presentations are more common and often delay the diagnosis. Associated tuberculosis meningitis has been described in 10 to 30% of adult patients with miliary tuberculosis.[41] Choroidal tubercles and cutaneous findings (tuberculosis cutis acuta generalizata) are highly specific, but insensitive for miliary TB.[41] Cutaneous manifestations are more commonly seen in HIV infected patients with advanced immunosuppression ($CD4^+$ cell counts <100 cells/cmm).[42]

TB through hematogenous dissemination can occasionally lead to sepsis and septic shock, it was known as Landouzy septicemia or sepsis tuberculosa acutissima in the past.[43] It is most commonly noted in immunocompromised patients, especially in patients with HIV, but may also occur in immunocompetent patients.[44]

HIV AND TB

Tuberculosis can involve HIV infected patients at all the levels of CD4 T-lymphocyte counts, but clinical and radiological manifestations depend on the severity of immunosuppression.[45] Majority of patients with CD4 counts >200 cells/cmm have disease limited to the lungs with common chest radiographic findings, such as upper lobe infiltrates with or without cavitation, not substantially different from HIV-negative patients. On the other hand, patients with advanced HIV disease (CD4 T-lymphocyte count<200/cmm) are more likely to have atypical presentation such as the lower lobe predominance, adenopathy and absence of cavities. Extrapulmonary and disseminated disease is common in advanced HIV infection, occurring in 63% of patients.[46] Severely immunocompromised patients can have sepsis like syndrome with high fevers[47] (See Chapter 51 for details).

PLEURAL EFFUSION

In primary TB, effusions typically develop three to six months after infection, are due to hypersensitivity response to a small amount of tuberculoprotein released into the pleural space.[48] Pleural effusion is less commonly seen in post primary TB, it is due to the rupture of a cavity or adjacent parenchymal focus into pleural space, releasing large number of bacteria in contrast to primary TB. In patients of pulmonary tuberculosis, pleural involvement appears to be more common in HIV coinfected individuals. Tuberculous pleuritis often presents acutely, shows significantly higher frequency of chest pain, dyspnea and abdominal pain, whereas hemoptysis and weight are less commonly noticed[49] (See Chapter 156 for details).

PARADOXICAL RESPONSE

Paradoxical response in tuberculosis includes the unusual expansion of old lesions or formation of new tuberculous lesion during antituberculosis therapy.[50] Paradoxical responses are known to occur in tuberculous pleural effusion, pulmonary tuberculosis, tuberculous lymphadenopathy and intracranial tuberculoma. Paradoxical worsening occurs with rapid mycobacterial killing and release of products that stimulate the T-helper subtype 1 (Th1) lymphocyte subpopulation, which in turn liberate various proinflammatory cytokines, including TNF-α, interleukin IL-2, IL-6 and IL-8, responsible for worsening of tuberculous lesions.[51] Paradoxical reaction is particularly common in up to 30% patients with cervical lymphadenopathy whereas it is rare in those with intrathoracic lymphadenopathy.[52]

PHYSICAL EXAMINATIONS

There are several reactive immunologic phenomena, such as erythema nodosum, erythema induratum, reactive arthritis and amyloidosis, associated with *M. tuberculosis* infections.[53] These are more common in primary TB. Erythema nodosum usually occurs acutely and is clinically characterized by the sudden eruption of erythematous tender nodules and plaques located predominantly over the extensor aspects of the lower extremities. It may occur in a disseminated form in severe reaction and heal without scarring. Erythema induratum, on the other hand, presents with a more indolent course, often precipitated by cold weather, tends to form blue plaques and heal with atrophic scars. Histologically, it is associated with vasculitis and granuloma formation.[54] Poncet's disease is a reactive arthritis characterized by aseptic inflammatory polyarthritis in the patients of active pulmonary TB, which tends to affect knees, ankles and elbows.[55]

Amyloidosis (AA type) may complicate chronic infections and tuberculosis is a common cause of secondary amyloidosis in the developing countries, can occur as early as two to four weeks after the diagnosis of active tuberculosis.[56] The pathogenesis of secondary amyloidosis involves the release of proinflammatory cytokines (such as interleukin (IL)-1, IL-6, and TNF-α), which stimulate the synthesis of serum amyloid in the liver and its subsequent deposition in various organs. This stimulation occurs even during the inactive stage of the disease.[57] Wasting is a classic feature of tuberculosis, caused by a combination of factors, e.g. lack of appetite, increased losses and altered metabolism as part of the inflammatory and immune responses.[58] Wasting also carries poor prognosis by causing increased mortality in patients with tuberculosis.[59] It is usually seen in advanced disease and indicates the loss of both fat and lean tissues.[58]

A major constraint of physical examination of respiratory system is its failure to detect mild or even moderate illness despite apparent radiographic abnormalities. Post tussive rales constitute an important sign, demonstrated on deep inhalation followed by full exhalation and coughing at the end of exhalation. Fine rales are heard over the areas of TB infiltrations, particularly at the apices. In endobronchial TB, localized wheezing may be heard. In tubercular consolidation, high pitched bronchial breathing, whereas in superficial large cavities, cavernous breathing may be audible. In tubercular pleurisy, pleural rub is often detected. Signs of volume contraction are often present in advanced disease with extensive fibrosis.

DIAGNOSIS OF TUBERCULOSIS

Routine Laboratory Testing

Mild anemia and leukocytosis are the most common hematologic abnormalities in TB. Anemia is caused by the inflammatory cytokines mediated suppression of erythropoiesis, most often described as normochromic, normocytic anemia, while some patients may show leukemoid reactions. Pancytopenia with hypocellular bone marrow has also been reported with *M. tuberculosis* infection.[60] Hematological manifestations are more common in disseminated/miliary tuberculosis patients. Patients of disseminated/miliary tuberculosis with granuloma in bone marrow showed significantly higher incidence of severe anemia, peripheral monocytopenia and bone marrow histiomonocytosis as compared to patients without granuloma.[61] In countries where TB is endemic, including in India, TB should be carefully excluded in patients presenting with various hematological manifestations.

Hyponatremia and hypercalcemia have been observed in tuberculosis. Hyponatremia is more commonly noticed in tubercular meningitis than in pulmonary TB, is due to Syndrome of Inappropriate Antidiuretic Hormone Secretion (SIADH). It has been reported in 7 to 10% of active TB cases.[62,63] In addition, hyponatremia in tuberculosis can be due to Addison's disease. Adrenal tuberculosis was reported in 6% of patients with active tuberculosis and bilateral adrenal involvement in 70% cases.[64]

Hypercalcemia is the other electrolyte abnormality in active TB, but symptoms of hypercalcemia are uncommon. Prevalence rate of hypercalcemia in different studies vary from 15 to 51%.[65] The most plausible theory is extra renal production of 1, 25-dihydroxycholecalciferol. Unfortunately, all these findings are nonspecific. Erythrocyte Sedimentation Rate (ESR) estimation is also an unreliable indicator of disease activity.

Early diagnosis of TB and initiation of optimal therapy is important not only for the patient, but is also equally so for the community to decrease the possibility of transmission of infection to others. Any diagnostic modality for tuberculosis should have certain desirable features:

- It should have acceptable sensitivity, specificity and predictive value.
- It should be quantitative and reproducible.
- Its turn around time should be rapid.

Further, the test should be cost-effective, safe, easy to use, and should perform equally well in resource poor settings and HIV prevalent areas. Laboratory testing for tuberculosis includes tests for latent tuberculosis infection as well as for tuberculosis disease. In latent TB infection, individuals are harboring live *M. tuberculosis,* but do not show any clinical evidence or signs and symptoms of active disease. Tuberculosis, on the other hand, is the clinically manifested illness caused by *M. tuberculosis* complex. Tests for Latent Tuberculosis Infection (LTBI) include Tuberculin Skin Test (TST) and Interferon-Gamma Release Assays (IGRA).

Latent Tuberculosis

Tuberculin Skin Test (TST)

Tuberculin skin test is the oldest diagnostic test still in use in the modern medical practice. The material used for this purpose is Purified Protein Derivative (PPD). It is injected intradermally, indicates delayed type hypersensitivity response in exposed individuals. In tuberculin test, the area of induration (not erythema is measured after 48 to 72 hours of administration of PPD). In India, induration of >15 mm is taken as positive TST in immunocompetant person with no known risk factors for TB. PPD despite being in use for a century, possesses many short comings, including low sensitivity particularly in immunocompromised individuals (elderly, malnourished, HIV infection and other immunosuppressive conditions). In HIV infected patients, a cut-off of ≥ 5 mm of induration is considered as positive response. Overall, 75 to 90% of patients with active TB react to TST.[66]

Tuberculin testing also lacks specificity since PPD is a mixture of more than 200 proteins derived from *M. tuberculosis*, many of which are shared by other mycobacteria, including the Nontuberculous Mycobacteria (NTM) and Bacillus Calmette Guérin (BCG) strain.[67] A systematic meta analysis, showed minimal effect of BCG vaccination received in infancy on TST, the effect was virtually nil beyond 10 years of vaccination.[68] NTM usually produce induration smaller than 10 mm in diameter and are a cause of false positive TST only in areas with the high prevalence of NTM infections. Despite the diminished specificity of the TST in BCG vaccinated individuals, the American Thoracic Society recommends to ignore vaccination history when interpreting TST.[69] Other shortcomings are the inter-reader and intra reader variability in reporting and the need for a return visit.

Tuberculin skin test does not distinguish between the latent infection and the active disease. To increase the specificity of TST, we need to purify antigens that are specific to *M. tuberculosis* complex. Recently, a recombinant antigen (DPPD, not present in NTM) encoded by a gene unique to the *M. tuberculosis* complex organisms, has shown some promise in increasing the specificity of skin testing in the diagnosis of tuberculosis.[70] Another potential antigen that has shown promise in skin testing is the *M. tuberculosis* Early Secreted Antigenic Target -6 (ESAT-6).[71]

Interferon Gamma Release Assays (IGRA)

Interferon gamma release assays are the new T-cell based assays that measure the interferon gamma release, by sensitized lymphocytes in response to specific *M. tuberculosis* antigens such as the ESAT-6 and Culture Filtrate Protein 10 (CFP10).[69] These antigens, encoded by genes in the Region of Difference-1(RD1), are present in *M. tuberculosis,* but are absent in BCG vaccine strain and most nontuberculous mycobacteria except *M. marinum, M.szulgai* and *M. kansasii*.[72] Different currently available assays are the Enzyme Linked Immunosorbent Assay (ELISA), such as QuantiFERON TB and QuantiFERON TB Gold assays and enzyme linked immunospot assay, e.g. T-SPOT TB assay. In general, these tests are more specific and potentially more sensitive than the traditional TST.[73] Result of IGRA is not affected by prior BCG vaccination. The IGRA does not require a return visit, has no variability of skin test readings and there is no induction of boosting phenomenon on repeat testing. High diagnostic sensitivity has also been observed in young children for T-SPOT TB test and in immunosuppressed populations for both T-SPOT TB test and to a lesser extent to QuantiFERON TB Gold.[74]

Use of IGRA tests cannot differentiate latent infection from active disease. This is particularly problematic in high TB burden countries where the prevalence of latent infection is very high. Reactivation of latent TB infection reflects an impaired immune response, at least temporarily; so IGRAs may be falsely negative at the time of the development of disease.[75] Sensitivity in active TB ranges from 64 to 92%. Thus, IGRAs can potentially miss 10 to 30% of active TB cases and are hence unsuitable for use as "rule-in" tests.[76] Sensitivity of IGRAs also varies between high and low burden countries, clearly emphasizing the need to perform large studies in different settings.[76] The higher cost and need for sophisticated instruments prohibit their widespread use in the developing countries. Chemokine Inducible Protein 10 (IP-10) is another potential biomarker, which can be used in the immunodiagnosis of *M. tuberculosis* infection. Combination of IP-10 and IFN-gamma also increases the detection rate for LTBI.[77]

Diagnosis of Pulmonary Tuberculosis

Chest Radiology

Chest radiography is an important tool in suspecting the diagnosis of pulmonary tuberculosis. Chest X-rays are mostly abnormal in immunocompetent patients, but may be normal in about 10 to 15% of HIV-infected patients. No radiological features are typical of tuberculosis various other lung diseases can radiologically mimic TB. Radiological manifestations have been traditionally described in children and adults on the basis of primary and post primary tuberculosis.[78] Recently, these agewise distinctions of radiological manifestations have been blurred due to several reasons. Primary infection can occur at any age in an endemic area, further, primary tuberculosis accounts for 23 to 34% of all adult cases of tuberculosis.[79] Cavitation, generally considered as a sign of reactivation, can occur even after primary infection. HIV infection is also responsible for atypical radiographic manifestations. Two recent studies based on genotyping *M. tuberculosis* isolates with Restriction Fragment Length Polymorphism (RFLP) also show that the radiographic features are often similar in both primary and reactivation TB.[80,81]

In primary tuberculosis, classical radiological features include the presence of parenchymal disease, lymphadenopathy, pleural effusion, miliary disease and atelectasis. Parenchymal disease affects the areas of greatest ventilation in the lung and the most common sites are the middle lobe, lower lobe and anterior segment of upper lobe; however, it can affect any segment.[82] Dense and homogeneous consolidations are generally observed, but nodular and linear pattern are also occasionally seen.[83,84] A right sided predominance of parenchymal lesion is often seen, reflecting greater statistical probability of an airborne infection involving the right lung. Lymphadenopathy usually unilateral, is the most characteristic radiological feature in primary tuberculosis.[85] Hilar and paratracheal regions are most commonly affected. The combination of parenchymal focus and lymphadenopathy is called "Ghon complex."[86] On contrast enhanced Computed Tomography (CT) scan, TB lymphadenopathy, particularly when more than 2 cm in diameter, shows the characteristic "Rim sign" consisting of the central areas of low attenuation associated with peripheral rim enhancement and obliteration of surrounding perinodal fat.[87] This corresponds to central caseation necrosis with inflammatory, hypervascular capsular and perinodal reaction and is highly suggestive of active disease.[88] However, rim sign may also be present in other conditions, such as atypical mycobacterial infection, lymphoma, metastases, particularly from testicular carcinoma, Whipple's disease and Crohn's disease.[84]

The radiological features of post primary tuberculosis can be broadly classified as the parenchymal miliary disease, cavitation (Figs 40.1 and 40.2), tracheobronchial TB, and pleural extension of parenchymal disease and complications. The most common sites for parenchymal opacities are apical and posterior segments of the upper lobe and the superior segment of the lower lobe. Multiple segments are affected in about 88% of cases, bilateral upper lobe disease observed in 32 to 64% cases.[89] Poorly defined nodules and linear opacities are seen adjacent to parenchymal opacities in approximately 25% of patients.[90]

Cavities are most commonly seen within the areas of consolidation and are reported in 40 to 50% cases of post primary tuberculosis.[86] Cavitation usually indicate active disease. The number of bacilli are in the order of 10^7 to 10^9, therefore, a high likelihood of sputum positivity is there in cavitary lesions.[91] One important feature, which differentiates tuberculosis from other cavitary diseases is the presence of clearly defined, nodular opacities around the cavity.[82] Most common complication of cavitation is the bronchogenic spread due to the liquefaction of caseous necrotic material and subsequent communication with the bronchial tree. On chest radiography, bronchogenic spread is detected in approximately 20% of cases, but on CT scans, it can be identified in 95% of cases with post primary TB.[84]

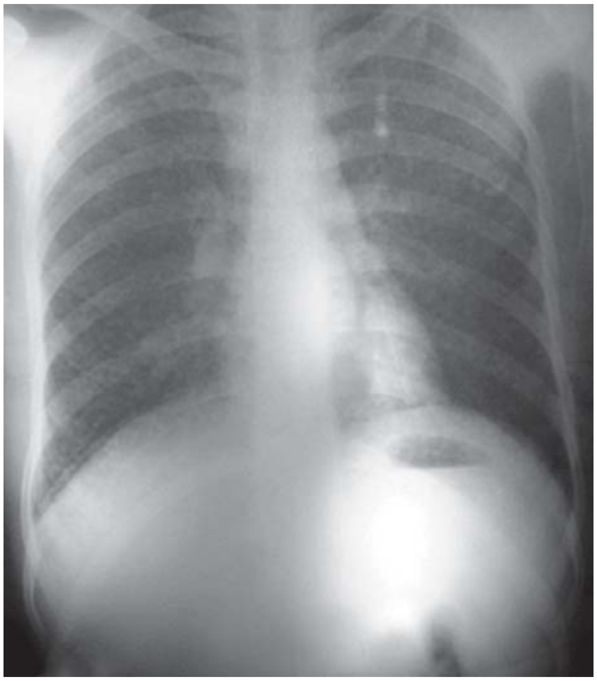

Fig. 40.1: Chest X-ray showing miliary shadow through both lung fields

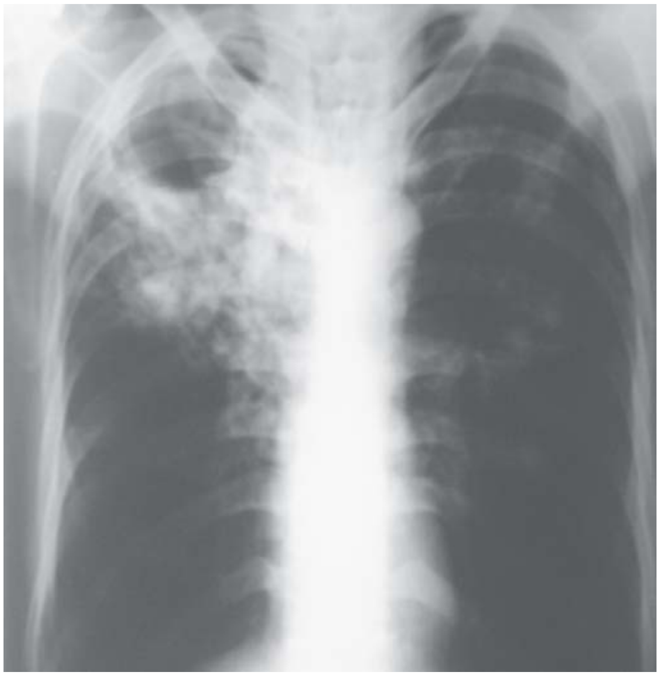

Fig. 40.2: Chest X-ray showing right upper lobe cavity with infiltration

Characteristics HRCT finding of bronchogenic spread is a "tree-in-bud" appearance, i.e. centrilobular nodules of 2–4 mm in size and sharply marginated linear branching opacities corresponding to the tuberculous involvement of the small airways. Air fluid level within tuberculous cavities may be seen in 9 to 21% of cases and usually indicates superimposed bacterial or fungal infection.[92-94] Hilar and mediastinal lymphadenopathy are not a common manifestation of post primary TB, occurs in only 5% of cases.[95]

Pulmonary TB with normal chest radiograph is increasingly being reported in the literature.[96] This is much more so in HIV positive persons (7 to 14%).[97-99]

The radiographic appearance of pulmonary tuberculosis is often "atypical" in HIV infected patients. It most commonly resembles with that of primary disease. Miliary disease and pleural effusion has been reported in up to 19 and 10% patients respectively.[99,100] Normal chest radiographs have been reported in 12 to 14% of HIV infected patients with smear or culture positive pulmonary tuberculosis.[99,100] Radiological manifestations may also depend on the degree of immunosuppression at the time of overt disease.

Chest CT is required in patients with high clinical suspicion of TB, but normal or nonspecific chest radiography. CT is more sensitive than chest radiography in detecting cavities, intrathoracic lymphadenopathy, miliary disease, bronchiectasis, bronchial stenosis and pleural disease. High Resolution Computed Tomography (HRCT) is superior to standard CT in the evaluation of pulmonary parenchymal disease.[101] In HRCT thorax, most commonly detected abnormalities in pulmonary TB are micronodules (100%) followed by "tree-in-bud" appearance (87%) and cavitation (73%).[102] The micronodules are typically centrilobular in location having indistinct margins. They are usually 5–6 mm in diameter, located in the peripheral parts of consolidations or cavities. Detection of micronodule is indeed highly suggestive of active tuberculosis.[101] Their presence indicates inflammatory lesions in the bronchioles and the peribronchiolar alveoli. Micronodules and "tree-in-bud" appearance are not detected by standard chest radiography. There is a significant correlation between consolidation and cavitation on conventional CT with increase in a number of bacilli in the sputum.[103] Consolidation pattern is also suggestive of active pulmonary TB, detected in 82% of patients.[102]

Tuberculoma is a sharply marginated round or oval lesion of 0.5–4.0 cm in diameter, detected in approximately 5% of patients with post primary TB. The location of tuberculoma has been variably reported in upper and lower lobes.[104] About 20 to 30% of tuberculomas in adults may ultimately calcify. In up to 80% of cases, smaller satellite lesions were seen in the immediate vicinity of the main lesion.[105] Tuberculomas are generally multiple, of similar size in 20% of cases.[106]

Miliary disease is less common in post primary than in primary TB.[79] Plain chest radiography can be normal in 25 to 40% of patients at initial presentation since typical miliary lesions need three to six weeks after hematogenous dissemination to manifest radiographically.[107] The typical radiological appearance is myriad, 1–3 mm, noncalcified nodules distributed throughout both the lungs, with mild basal predominance (Fig. 40.3). Other associated radiological features include consolidation, cavitation, calcified lymph nodes and lymphadenopathy observed in up to 30% of patients.[107] HRCT can detect miliary disease before it becomes apparent on standard chest radiography. Intralobular and interlobular septal thickening and areas of ground glass opacity may also be present. A diffuse alveolar pattern has been described in the patients of adult respiratory distress syndrome due to miliary TB.[108]

Sputum Microscopy

Sputum microscopy, the most widely available test for active TB, is the diagnostic centerpiece of the Directly Observed Treatment Short Course (DOTS) strategy. It is cheap, rapid, easy to perform and widely available diagnostic procedure to detect mycobacteria in clinical specimens. However, there are certain limitations of sputum microscopy. Sputum microscopy is not a highly

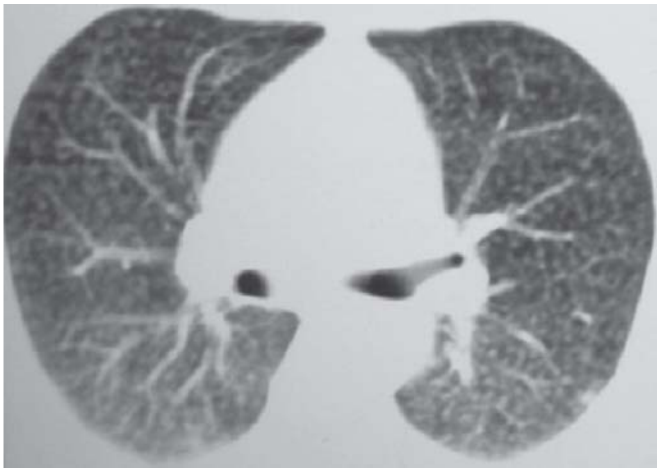

Fig. 40.3: HRCT Thorax showing miliary shadow through both lung fields

sensitive tool, it requires a minimal of 5,000–10,000 bacilli per ml of sputum to reliably identify the bacilli.[109] It can not differentiate *M. tuberculosis* from other mycobacteria. Sputum microscopy may also fail to diagnose paucibacillary and extrapulmonary tuberculosis, the incidence of which is disproportionately higher in high HIV prevalent areas. The sensitivity of sputum microscopy ranges from 34 to 80%.[110] The smear is more likely to be positive in patients who have cavitary disease and multilobar infiltrates. The result of smear microscopy is influenced by several variables like type of the specimen, thickness of the smear, technical preparation of the slide and experience of the laboratory personnel examining the smear.

Sensitivity of sputum microscopy is increased if sputum is liquefied and concentrated by centrifugation or sedimentation prior to acid fast staining.[111] In a systematic review of 83 studies, it has been demonstrated that sputum processed by centrifugation and use of various chemicals increased the sensitivity of microscopy by 18% compared to direct smear microscopy.[112] The most widely studied sputum processing method is liquefaction of sputum with sodium hypochlorite usually known as household bleach (NaOCl), followed by centrifugation or sedimentation. There are several advantages of using NaOCl; it is widely available and kills both the mycobacteria and HIV, therefore, tends to increase the safety and acceptability in the laboratory. However, this technique is not suitable for sample intended to be used for culture. Studies done in Ethiopia have reported that a single digested smear can equal the sensitivity of three direct smears.[113] Furthermore, there are certain limitations of these procedures, particularly in the context of resource limited, high prevalence countries. Irregular power supply, potential biohazard of centrifugation, and limited human and financial resources may impede its widespread applicability in the developing countries. Moreover, there is insufficient data to determine the value of sputum processing methods in HIV infected patients.

There are several staining methods such as the Ziehl-Neelsen, Kinyoun's (cold staining) and fluorescent staining methods.[114] The core principle of these methods is based on the avidity of the lipid rich cell wall to different dyes. In Ziehl-Neelsen method, heat is applied to encourage the cell wall to take up the stain followed by decolorization with acid or acid alcohol, and finally counterstaining with methylene blue or malachite green. In cold Kinyoun's method, higher concentrations of phenol and basic fuchsin are used.[114] The mycobacteria in these staining methods appear red against blue or green background. Performance of Kinyoun's stain has been reported to be inferior to that of Ziehl-Neelsen stain in several studies.[115,116] Other microorganisms that may take up acid fast stains, albeit weakly, are Rhodococcus, Nocardia, Legionella micdadei, and cysts of Cryptosporidium, Isospora, and Cyclospora.

Fluorescence microscopy requires staining with the dye auramine rhodamine. The mycobacteria appear bright yellow rods against inky black background. There are several advantages of fluorescent microscopy over conventional staining methods:[117]

- Rapid turnaround time with fluorescence microscopy as it uses a lower power objective lens (typically 25X) than conventional microscopy (typically 100X), allowing much faster reading of specimens than smears stained with the Ziehl-Neelsen method. It takes one to two minutes per slide in contrast to 15 minutes required for Ziehl-Neelsen staining method
- It is more sensitive than conventional microscopy. In comparison with Ziehl-Neelsen microscopy, fluorescence microscopy has shown a 10% increase in sensitivity. The major problem of its implementation in the developing countries is the cost of fluorescent bulb, which is costly and is of a short life span (typically 200–300 hours). The use of light emitting diodes as a light source is an attractive, inexpensive alternative to mercury vapor lamps.[118]

In recently revised policies on smear microscopy, WHO now recommends two sputum specimens examination instead of three for screening of TB cases, in places where a well functioning external quality assurance system exists and where the workload is very high and human resources are limited.

Smear microscopy is likely to retain its pivotal role in the diagnosis of TB in major parts of the world. Optimization of smear microscopy should be an important goal of any tuberculosis control program. Smear negative patient who is unable to produce sputum, should undergo further diagnostic testing such as Sputum Induction (SI), Fiberoptic Bronchoscopy (FOB) and sometimes Gastric Washings (GW).

Induced Sputum Examination

There are several advantages of sputum induction:

- Diagnostic yield of single induced sputum is atleast equivalent to that of one bronchoscopy with Bronchoalveolar Lavage (BAL) in the terms of positivity on both smear and culture for mycobacteria.[119,120] The diagnostic yield of induced sputum can be increased with significantly higher detection rates than with bronchoscopy alone when multiple (three or more) specimens are used. Smear microscopy and culture positivity rates of 91 to 98% and 99 to 100% respectively, have been reported with multiple specimens.[121]

- Induced sputum is a very safe procedure with extremely few adverse events, unlike invasive procedure such as bronchoscopy. Most common adverse events are headache, bronchospasm/cough and the risk of transmission of TB to attending staff, if appropriate protection measures are not applied
- Cost analysis studies also favor sputum induction over bronchoscopy[122]
- Sputum induction performs equally well in both resource poor and resource rich countries and is also useful in HIV positive and negative patients.[114]

Therefore, sputum induction should be used as the primary modality in patients who are either unable to provide spontaneous sputum samples or who are AFB smear negative.[123] Sputum induction has been shown to improve sputum microscopy result by 29% in patients with suspected TB who previously had negative smear.[124] It is also superior to gastric aspirate specimens in the terms of sensitivity and speed to culture positivity.[125]

Fiberoptic Bronchoscopy (FOB)

The main role of FOB in diagnosing pulmonary tuberculosis includes patients who are sputum smear negative for AFB or who do not produce adequate sputum, particularly if an immediate diagnosis is required or if alterative diagnoses are being entertained. It is also useful for follow-up studies in endobronchial tuberculosis to detect bronchostenosis. Different bronchoscopic modalities to obtain samples include the bronchial aspirate, bronchoalveolar lavage, brushings, Transbronchial Lung Biopsy (TBLB) and Transbronchial Needle Aspiration (TBNA). Among the various bronchoscopic procedures to retrieve samples, the yield of BAL for *M. tuberculosis* is superior to that of bronchial washings.[125] The higher yield in BAL is due to the large quantity of saline used in BAL, which lowers the concentration of aspirated local anesthetic, which can inhibit the growth of *M. tuberculosis*. A small amount of 2 ml of 2% lignocaine can produce a bronchial aspirate concentration of up to 1% at which most strains of *M. tuberculosis* are inhibited.[126,127]

Culture of TBLB and bronchial brushing specimens provide little additional yield. Various studies using FOB as a modality, have demonstrated early diagnosis in 4 to 79% cases and exclusive diagnosis in 2 to 52% cases.[126] FOB use in high prevalent areas of TB has successfully led to early diagnosis in a larger percentage of patients (72 to 73%).[128,129]

Use of FOB in miliary TB seems particularly attractive because of inherent problems with conventional diagnostic procedures. Presence of miliary mottling on chest radiography varies from 50 to 93% of cases.[130,131] Smear microscopy and sputum cultures are positive in one-third and less than two thirds of patients respectively.[131] Delay in diagnosis can be associated with significant mortality in miliary tuberculosis. Using FOB, immediate (or early) diagnosis (positive AFB smear, transbronchial biopsy specimens revealing caseating granulomas with or without AFB) can be achieved.

FOB is also useful in the diagnosis of tuberculous intrathoracic lymphadenopathy by using TBNA technique. Incidence of isolated intrathoracic tuberculous lymphadenitis varies from 0.25 to 5.8%, poses a diagnostic challenge. FOB in tuberculous intrathoracic lymphadenopathy also helps because of the presence of endobronchial involvement in a large percentage of patients (75%), which also explains frequent erosion of bronchial tree by intrathoracic tuberculous lymphadenopathy.[132] Endobronchial ultrasound is another tool, which can further ease the procedure of TBNA.

Mycobacterial Cultures

Mycobacterial culture is the gold standard for the diagnosis of tuberculosis. It is more sensitive than sputum microscopy, requires 10–100/ml organisms to detect *M. tuberculosis*.[110] About 25 to 60% of patients with culture positive pulmonary TB may show negative smears. Sensitivity and specificity of culture is 80 to 93% and 98% respectively.[110,133] Culture not only increases the sensitivity of *M. tuberculosis* diagnosis, but also helps in species identification, drug susceptibility testing and genotyping.

Culture media are of various types: Solid media, which can be egg based (Lowenstein-Jensen) or agar based (Middlebrook 7H10 and 7H11) media; and liquid media (Middlebrook 7H12 and other broths). Most laboratories in the developing countries use solid media for mycobacterial culture. The greatest isolation rates are obtained from a combination of solid and liquid media. The main constraint of solid media is long time required for growth (mean time of at least four weeks). Other problems in the developing countries are the nonavailability and the inaccessibility of reliable laboratories for good quality cultures. Liquid culture media based on

Middlebrook 7H12 broth give faster results than the solid media. They are also more sensitive than solid media for the detection of mycobacteria and may increase the diagnostic yield by 10%.[134,135] Disadvantages of liquid culture media include a high risk of contamination and the lack of colony morphology examination, which may help in detecting unexpected growth of non TB mycobacteria.

Following are the rapid culture methods which are available:

i. *BACTEC (Becton Dickinson) culture medium:* A BACTEC 460 radiometric system (Becton Dickinson Instrument Systems, Sparks, MD, USA) is an automated method. It is based on the measurement of $^{14}CO_2$ liberated from ^{14}C palmitic acid by metabolizing mycobacteria. There is a rapid turn around time with 87% of positive cultures recorded at 7 days and 96% by 14 days.[136] Major constraints with this method are the high costs and the problem of disposal of radioactive materials.

ii. *Mycobacterial Growth Indicator Tube (MGIT):* MGIT is a nonradiometric system. It contains Middlebrook 7H9 broth and a fluorescent compound embedded in a silicone sensor, which is sensitive to oxygen consumption in the medium emitting luminescence. Growth is detected visually using the ultraviolet light. Both manual and automatic (BACTEC MGIT 960) systems are available. Results are comparable to that of BACTEC 460 radiometric system.[137] The mean time for the detection of growth of mycobacteria in MGIT ranges from 8 days to 16 days.

iii. *Microcolony detection on solid media:* Growth of mycobacteria is detected by microscopic examination of plates covered with the thin layer of Middlebrook 7H11 agar medium. Though this technique is less expensive and requires lesser time than conventional culture, recovery of mycobacteria is less efficient and labor intensive.

iv. *Septi check AFB method:* It is biphasic culture system made up of a modified Middlebrook 7H9 broth with a three sided paddle containing chocolate, egg based, and modified 7H11 solid agar. The growth is observed by the three sided paddle. The main characteristic of this system is the simultaneous detection of *M. tuberculosis*, nontubercular mycobacteria and even, contaminants.

v. *MB/BacT system:* This is a nonradiometric system based on the colorimetric detection of CO_2. The disadvantages are the increased contamination and slightly longer time required for the detection of growth as compared to BACTEC 460 system.[138]

vi. *ESP II culture system:* This is a fully automated continuously monitoring system based on the detection of pressure changes in the culture medium of a sealed vial during mycobacterial growth. It should be used in combination with solid medium only.

vii. *Microscopic Observation of In Broth Culture (MODS):* It is suitable for high tuberculosis burden country, but it requires high laboratory biosafety, relatively costly media, antimicrobial supplements and high technical skills.

EXTRAPULMONARY TUBERCULOSIS (EPTB)

In immunocompetent adults, EPTB constitutes about 15 to 20% of all cases of TB, whereas in HIV positive patients, it accounts for more than 50%.[139] The commonly reported extrapulmonary sites of tuberculous involvement are the lymph nodes, pleura, bones or joints, and Central Nervous System (CNS). However, it can involve any organ. Lymph node tuberculosis is the commonest form of EPTB in India and other developing countries.[130]

Diagnosis of EPTB can pose a challenge to the clinicians due to various reasons:

- Signs and symptoms are most often nonspecific
- Paucibacillary nature of samples decreases the sensitivity of diagnostic tests
- EPTB involves relatively inaccessible sites so the retrieval of samples for diagnosis is a difficult job.

In a retrospective study done in Tanzania involving patients with extrapulmonary tuberculosis, bacteriological or histological confirmation of diagnosis was possible in only 18% cases.[140] So misdiagnosis is common in almost all countries, which may lead to unnecessary presumptive treatment in patients without TB, or greater morbidity and mortality if the diagnosis of TB is delayed, especially in persons with concomitant HIV infection.

Microscopic examination of sputum and culture lacks sensitivity in extrapulmonary disease. In a prospective study in Malawi, sputum positivity rate in EPTB patients was dismal (1.7%).[141] But, in some form of EPTB, e.g. pleural TB, sputum samples may be beneficial. Conde et al.[142] reported a remarkably high yield of mycobacterial culture (52%) in a single specimen of induced sputum with sputum smear-positivity in 12% of cases. Therefore, resource limited countries where invasive diagnostic procedures are less accessible, sputum induction should be advised.[143]

Chest radiology may sometimes provide useful clue of the presence of associated pulmonary TB and may obviate the need for further invasive diagnostic modality in the developing countries. Abnormal chest radiography has been reported in 5 to 44% of lymph node tuberculosis, 30 to 50% of pleural effusion, 20 to 28% of abdominal tuberculosis and 32% of pericardial TB patient's respectively.[143]

Adenosine Deaminase (ADA) enzyme estimation especially in pleural fluid has shown great promise in the diagnosis of tubercular pleural effusion. In pleural effusion, sensitivity and specificity of ADA have varied from 85 to 100% and 80 to 97% respectively.[144] ADA levels are also elevated in a number of extrapulmonary sites in patients with TB, including Cerebrospinal Fluid (CSF) and BAL. However, the utility of measuring ADA levels in these fluids has not been rigorously studied.

Molecular Diagnosis of Tuberculosis

Mamta Kalra, Indu Verma, Suman Laal

INTRODUCTION

Only 5 to 10% of the individuals who get infected with *Mycobacterium tuberculosis* (*M. tb*) progress to clinical TB;[1,2] the remaining individuals who get infected develop immune responses that arrest the progression of the infection to clinical TB, although they continue to harbor a Latent Tuberculosis Infection (LTBI). Approximately, 10% of the latently infected subjects reactivate their LTBI and progress to clinical TB sometime later during the years/decades postinfection. Despite this relatively limited progression of *M. tb* infection to clinical disease, more than 8 million new cases of TB occur every year and approximately two million individuals die because of TB.[3,4] The spread of Human Immunodeficiency Virus (HIV)-infection in the TB endemic countries and the synergistic relationship between HIV and TB is further accelerating the morbidity and mortality caused by TB.[4] The WHO has implemented Directly Observed Therapy Short-term (DOTS) programs for TB diagnosis and treatment in most parts of the world. However, the success of the DOTS programs is hampered by the lack of rapid and accurate diagnostic tools.

DIAGNOSIS OF TB IN LOW-INCOME COUNTRIES

Tuberculosis is a chronic, slow progressing infection (except in immunocompromised individuals), which can manifest as pulmonary or extrapulmonary disease. Even pulmonary TB is not a single-stage acute disease and patients present with a spectrum of clinical, radiological and bacterial indications.

There is no single diagnostic test that can detect TB at all the different stages or the different forms of TB, a combination of clinical suspicion, microscopic examination of smears made directly from sputum for presence of Acid-fast Bacilli (AFB) and radiological findings are used for diagnosis. Clinically, TB can present with symptoms that vary from mild cough or chest pains in an otherwise asymptomatic patient to fever, night sweats, wasting, hemoptysis, etc. and therefore, often does not provide unambiguous diagnosis. Acid-fast bacilli microscopy is highly specific and low-cost,[5,6] but visualizing bacteria in smears made without processing and concentration of sputum specimens requires the presence of 5 to 10 thousand AFB per ml of the sputum; this occurs only when the patient has progressed to advanced disease.

Microscopy requires careful examination of multiple specimens from each patient, which is tedious and requires good microscopes; factors that decrease sensitivity in settings that have high patient burden and meager resources. As a result, the sensitivity of the AFB smear test varies from 30 to 80% in culture confirmed TB in different laboratories. Microscopy fails to identify about 50% of the patients who have less advanced disease (smear negative) and performs poorly in pediatric cases, patients with extrapulmonary TB and HIV-infected TB patients. Thus, AFB smear-based diagnosis results in significant under-diagnosis of TB, resulting in increased morbidity and mortality and continued transmission into the communities.[6] Chest X-rays can aid diagnosis when the disease is advanced, but their utility is limited by patient variability in that there may be no pulmonary involvement, or patients may have a typical infiltration or may have progressed to different levels of cavitation and pulmonary damage. Culture of AFB although can enhance the sensitivity of diagnosis, permits identification and drug sensitivity testing of isolated mycobacterial species. However, because *M. tb* is a slow growing pathogen, cultures require several weeks (6 to 8 weeks) and are significantly more expensive than microscopy. In developing countries, culture is not a feasible option because of the high patient burden and the requirement for expensive laboratory infrastructure and the associated expenses. Rapid and simple tests that can replace AFB microscopy, and can improve diagnosis of paucibacillary TB are urgently required.

DIAGNOSIS OF TB IN HIGH-INCOME COUNTRIES

The speed and accuracy of TB diagnosis is significantly better in the resource-rich countries (US, Western Europe, etc.) that have a low incidence of TB. Microscopy has significantly improved sensitivity because the smears are prepared from sputum samples that are digested, decontaminated and concentrated; fluorescence microscopy, which is more sensitive, is routinely used. Culture of bacteria on solid (Middlebrook, Lowenstein-Jensen) and/or liquid media complements microscopy and several sensitive broth-based culture systems are routinely used (Becton, Dickinson and Company, Sparks; MB/BacT, Organon Teknika Corporation, NC; ESP, TREK Diagnostic systems Inc, Cleveland, OH; Wampole laboratories, Princeton, NJ; etc). Fully automated systems where the vials inoculated with the patient specimen are monitored continuously for bacterial growth are available in most mycobacteriology labs. Coupled with the highly sensitive and specific nucleic acid amplification tests (NAAT, GenProbe, San Diego, Ca; Amplicor, Roche, Basel, Switzerland) that are available for the confirmation of *M. tb*, the sensitivity of TB diagnosis of multibacillary TB cases in these countries is very high (95 to 98%) and a large proportion of paucibacillary cases (48 to 53%) are also detected.[7,8]

Despite the use of multiple diagnostic methods, diagnosis of smear negative TB cases can take several weeks as chest X-rays/CT scans and microscopy take several days and another 7 to 14 days are required for culture confirmation even in smear-positive patients. Additional sensitive methods for the identification of *M. tb* from liquid cultures are available (HPLC, GLC) and may be useful for the difficult-to-diagnose cases, but the costs and complexity limit their use in routine diagnosis. Despite the use of multiple tests, no bacteriological confirmation can be obtained for approximately 10 to 20% of the TB patients, who are determined to have TB based on clinical and/or radiological improvement while on anti-TB medications.[9] Clearly, there is a definite need for improved diagnostic tests even for the resource-rich countries and tests that can rapidly identify paucibacillary TB would be an asset to TB control.[1,10]

Detection and treatment of LTBI is an integral component of TB control in the high-income settings. The detection of LTBI is based on the Tuberculin Skin Test [TST; also called the purified protein derivative (PPD) skin test], which measures delayed hypersensitivity responses elicited by the mycobacterial antigens.[2] Because PPD is actually a crude mixture of more than 200 different secreted and somatic proteins of *M. tb*, many of which are shared among Nontuberculosis Mycobacteria (NTM) and *Mycobacterium bovis* Bacillus Calmette-Guérin (BCG), the specificity of the PPD test is low, especially in individuals vaccinated with BCG or cross-sensitized with nonpathogenic environmental mycobacteria. The sensitivity of the PPD test is also suboptimal and it fails to identify approximately 20 to 30% of confirmed TB cases. Although PPD testing is relatively inexpensive, it fails to differentiate between a latent infection that may never progress to clinical TB and active subclinical or clinical TB[11-13] and cannot predict if and when the infection will progress to clinical TB. As a result, even though approximately 5 to 10 % of the *M. tb* infected individuals actually progress to clinical TB, all PPD-positive individuals require clinical, bacteriological and radiological evaluation and individuals believed to be infected and at risk for TB are required to take preventive therapy with Isoniazid (INH) for six to nine months.[2] Thus, PPD test-based decisions result in treatment of latent infection in individuals who may never progress to clinical TB, monotherapy in individuals who may have an active but subclinical infection or are infected with INH-resistant *M. tb* and no treatment in infected individuals with false negative responses.[2]

According to the CDC estimates, there are approximately 15 million latently infected individuals in the US, and better diagnostic tests that can accurately identify *M. tb* infection and can discriminate between latent and incipient subclinical TB in high risk populations are required to eliminate TB from the US.[10,14] More accurate diagnostic tests for M. tb infection, the Interferon Gamma Release Assays (IGRAs; described below) have become available in recent years and are increasingly being used in these countries instead of TST.

TB DIAGNOSIS IN HIV+ INDIVIDUALS

The immune dysfunction caused by HIV infection leads to increased reactivation of latent TB, increased incidence of primary TB and accelerated course of disease progression in HIV+ individuals.[15-19] The risk of developing TB doubles as early as in the first year after acquiring HIV infection and continues to increase in subsequent years.[20] As a result, in sub-Saharan Africa and Southeast Asia where TB is endemic, approximately 50 to 70% of the HIV+ individuals develop TB.[4,21-24] Concomitant TB accelerates the progression of HIV infection.[15,16] The dysfunctional cellular immune responses in HIV+ patients result in reduced pulmonary pathology and progression to cavitary lesions, which in turn results in reduced smear positivity. For these reasons, the limitations of the current diagnostic tests for TB are amplified in HIV coinfected individuals.[25] TB is thus the single most important cause of morbidity and mortality in HIV+ patients in TB-endemic countries. As in nonHIV *M. tb* infected individuals, preventive therapy with INH in HIV co-infected individuals with latent *M. tb* infection has also been shown to reduce the risk for developing TB.[1]

In TB-endemic countries the rates of latent infection are high, preventive treatment with anti-TB drugs, and the accompanying clinical, bacteriological and adherence monitoring is impossible, and treatment of unrecognized active TB with one or two drugs enhances the risk of fostering drug resistance.[26-28] For these reasons, preventive treatment for HIV-infected persons is not recommended in these settings unless active TB can be ruled out on the basis of clinical evaluation.[29,30] No diagnostic tests that can discriminate between latent TB and incipient, subclinical TB in HIV-infected individuals are currently available. This is problematic because undiagnosed active TB in asymptomatic HIV+ patients with no clinical, radiological or bacteriological indications of TB has been reported from several settings.[18,19] Thus, tests that can rapidly discriminate between LTBI and incipient subclinical TB and identify patients with subclinical TB prior to progression to bacteriologically detectable, clinical TB are urgently required. Such a test would prevent progression of *M. tb* infection to clinical TB, contribute to interruption of transmission into communities, and retard the progression of HIV-infection in patients who are unable to obtain antiretroviral therapy.[27]

DIAGNOSIS OF TB: BEYOND MICROSCOPY

Direct sputum microscopy has been used for TB diagnosis since the 1880s and it remains the primary tool for TB diagnosis, 120 years later. More sensitive and specific diagnostic tests have emerged in the last few decades, but are too expensive and technically challenging for implementation in the high burden, low-resource settings. While an unprecedented interest has arisen in devising new diagnostic tools for TB in the last decade or so, and some new tests have been devised, there is still a significant lack of tools that will be required to control and eliminate TB. An overview of the diagnostic tests that are used in the developed world or are currently under development is provided (Table 41.1).

Nucleic Acid Amplification (NAA) Detection Based Diagnostic Tests for TB

The use of NAA based diagnosis has led to significant improvement in rapid diagnosis of TB in the resource-rich countries. Several commercial NAA tests are currently available, each using a different method to amplify a

TABLE 41.1: Molecular methods used for diagnosis of tuberculosis

1. Nucleic acid amplification (NAA) detection based tests
    i. Amplified MTB Direct test (MTD)

specific region in *M. tb* genome. These include: The Amplified *M. tuberculosis* Direct test (MTD, Gen-Probe Inc, CA), the Amplicor M tuberculosis test (Amplicor), the COBAS Amplicor MTB test, the COBAS Taqman test MTB (Roche Diagnostics Inc, NJ) and the BD ProbeTec MTB test (Becton Dickinson, MD). Of these, the MTD test was the first NAAT approved by the United States Food and Drug Administration (FDA) in 1995 for *M. tb* detection in AFB smear-positive respiratory specimens. Later, in 1999, a second-generation MTD (enhanced MTD or E-MTD) test was approved for use in respiratory specimens from all patients suspected to have TB regardless of their smear status.[31] The Amplicor *M. tb* test was approved by the FDA in 1996 for testing in AFB smear positive TB patients using respiratory specimens only.[31]

The MTD test is based on isothermal amplification of 16S rRNA transcripts (transcription mediated amplification, TMA) that is detected using acridinium ester labeled *M. tb* complex-specific DNA probes in a hybridization protection assay.[32] The entire process is carried out at 42°C. Although entirely manual, the test is rapid with a turnaround time of about 2.5 hours. The results however, require a luminometer for interpretation. Several studies have confirmed the sensitivity and specificity of MTD test; the sensitivity ranges between 90 to 100% in smear-positive and 63 to 100% in smear-negative specimens.[33] Enhanced-MTD, the modified version of the original MTD test, uses larger sample volume, requires less processing time and is simpler to perform due to the elimination of hybridization controls and amplification termination step.[34] Both MTD and E-MTD are highly specific (>95%) however, sensitivity of E-MTD has been shown to be higher than the original MTD test.[35,36]

The Amplicor is a DNA-based test that amplifies 16S rRNA gene using genus-specific primers followed by hybridization to specific probes. The binding of probes is detected by a colorimetric reaction in a microwell plate format.[37] Turnaround time for the Amplicor test is six to seven hours. The Amplicor MTB test provides 90 to 100% sensitivity in smear-positive respiratory samples and 50 to 95.9% in smear negative samples. Overall specificity has been reported in the range of 90 to 100%.[33,38] An automated version of the test, the COBAS Amplicor is also available that uses the COBAS Amplicor analyzer and allows rapid amplification and detection in one system.[39] A qualitative COBAS TaqMan MTB test based on integration of real-time PCR technology with standard hybridization is also available. The turnaround time for analyzing 48 samples simultaneously using COBAS TaqMan is 2.5 hours.[38] Recent studies suggest that accuracy of COBAS TaqMan is superior to Amplicor for detecting *M. tb*, but the test is not yet approved by FDA.[40,41]

BD ProbeTec MTB test (Becton Dickinson, MD) is another commercially available test for the direct detection of *M. tb*. It is a semiquantitative assay that involves strand displacement method for enzymatic amplification of target sequences located in IS6110 and 16s rRNA genes.[42] The products of amplification are detected using a luminometer. The test has shown high sensitivity in both smear-positive (100%), as well as smear-negative (92 to 100%) patients using respiratory samples.[42,43] However, the sample preparation is time consuming. An improved version of BD ProbeTec ET that includes an internal amplification control to detect the presence of inhibitors showed higher sensitivity in smear-positive than smear-negative samples.[44] This test also awaits approval from FDA.

The CDC guidelines recommend that "NAA testing be performed on at least one respiratory specimen from each patient with signs and symptoms of pulmonary TB for whom a diagnosis of TB is considered but not established and for whom the test result would alter case management and TB control activities."[31] However, because all the current tests require trained personnel, specialized equipment and are expensive, they are rarely used in the TB-endemic countries and cannot be integrated into routine patient care.

Efforts to develop cheaper, simpler and less technology-oriented NAA-based molecular tests are ongoing. A Loop-Mediated Isothermal Amplification (LAMP) (Eiken Chemical Co., Japan) test has been developed for simple and sensitive detection for TB.[38] The technique involves autocycling strand displacement DNA synthesis using the large fragment of *Bacillus stearothermophilus* DNA polymerase. Pyrophosphate produced as a byproduct during DNA synthesis in LAMP assay is visible as a white precipitate of magnesium pyrophosphate in the reaction vial. DNA detection is based on presence or absence of the precipitate.[45,46] Moreover, the turbidity of the reaction mixture is directly proportionate to the amount of DNA synthesized. The entire procedure is carried out in a single tube by incubating very small volume of DNA at 63°C for 1 hour. A prototype LAMP assay with simplified manual DNA extraction method to detect *M. tb* in respiratory samples has been used for clinical evaluation in peripheral microscopy centers in Peru, Bangladesh, and Tanzania.[47] The test outperformed microscopy in these studies and demonstrated the feasibility of performing the assay without the use of sophisticated equipment and specialized training.[47,48] More extensive field evaluations of the assay are under way.

Several in-house assays employing simple PCR as well as real-time PCR-based techniques have been reported from different laboratories for the diagnosis of TB. PCR based in-house NAA tests involve amplification of either various target DNA or RNA sequences followed by detection using agarose or acrylamide gel electrophoresis or by hybridization.[49-53] Real time PCR is a quantitative method based on the hybridization of the amplified segments (DNA) with different fluorescent probes, such as TaqMan probes Fluorescence Resonance Energy Transfer (FRET) probes molecular beacons and bioprobes.[54,55] The intensity of fluorescence is detected in a thermal cycler and is directly proportional to the amount of amplified product in the reaction tube. The main advantage of Real time PCR is its speed to yield the results reducing the time to 1.5 to 2 hours after DNA extraction. In addition, the problems with cross contamination are less likely as detection takes place in a closed system. The adaptation of these in-house assays to commercial formats is awaited.

Tests for Species Identification of Mycobacteria

Prompt identification of *Mycobacterium* species has become increasingly important with the increase in NTM infections, especially in HIV-infected individuals.[56] NTMs require a different treatment regimen and a lack of response to standard antituberculous drugs can be confused with drug-resistance.[57] Thus, adequate disease management requires precise classification of mycobacteria. Conventional methods of *Mycobacterium* species identification include biochemical tests and phenotypic characteristics that are simple and do not require any sophisticated equipment, but these tests are laborious and cumbersome, and take several days for results, thus delaying prompt and accurate identification of bacteria. Newly developed molecular methods are attractive alternatives for rapid identification of mycobacteria, especially *M. tb* complex. Several molecular commercial tests are available for rapid identification of mycobacterial species from culture isolates.[58] These include the MicroSeq 500 system (Applied Biosystems, Foster City, CA), AccuProbe assay (Gen-Probe Inc, CA), INNO-LiPA Mycobacteria (Innogenetics NV, Belgium), GenoType MTBC and GenoType Mycobacterium (Hain Lifescience, Nehren, Germany).

The MicroSeq 500 is a microbial identification system based on sequencing of a 16S ribosomal DNA. The test has shown high sensitivity with clinical isolates, but is time consuming and requires sophisticated instrumentation for data analysis.[59,60] The AccuProbe assay, one of the first introduced and the most widely used molecular technique for species identification, utilizes species specific DNA probes. Hybridization of these probes with species specific target rRNA sequences can differentiate and identify *M. tb* complex, *M. avium, M. intracellulare, M. avium complex*, *M. kansasii* and *M. gordonae*.[61-66] The sensitivity and specificity of these probes is reported to be more than 90%.[38] The turnaround time using AccuProbe on culture is two hours, but the test can identify only a limited number of species and is unable to differentiate *M. tb* from the other species in the complex.[67]

The INNO-LiPA Mycobacteria v2 (Innogenetics NV, Belgium) system for mycobacterial species identification simultaneously detects and identifies the genus *Mycobacterium* along with 16 different species. It is a line probe assay based on nucleotide differences in the 16s–23s rRNA gene spacers. The test can be performed on liquid or solid cultures and shows high specificity (94%) and sensitivity (100%)[68-70] in a variety of mycobacterial species. The other two commercially available molecular systems, GenoType MTBC and GenoType Mycobacterium use reverse line probe hybridization assays to identify mycobacterial species and differentiate members of the *M. tuberculosis* complex.

The basic technique for both the assays involves PCR amplification followed by the hybridization of the amplified products to specific oligonucleotide probes immobilized on the membrane strips. The interpretation is based on the appearance of bands in specific combinations. The GenoType *Mycobacterium*, based on regions of 23s rRNA, is able to identify 35 different species of mycobacteria, including *M. tb*.[38,71] The GenoType MTBC uses 23s rRNA fragment and gyrB sequence polymorphism to differentiate members of *M. tb* complex. Further, it targets RD1 deletion for identification of *M. bovis* BCG.[72] The GenoType MTBC test has been widely used for the speciation of mycobacteria in different studies and shows consistently high sensitivity and specificity.[73-75] However, these assays are labor intensive, require extensive training and being culture dependent, are restricted to use in reference laboratories.

In addition to commercial molecular tests, several in-house assays have been reported for mycobacterial species identification. These include sequencing of DNA fragments from various conserved and hypervariable regions of mycobacterial genome, such as 16s rRNA,[76] 23s rRNA,[38] 65-kDa heat-shock protein encoding gene[77] rpoB,[78] SoDA[79] and recA.[80] PCR- restriction length polymorphism has also been studied using hsp65[81,82] rpoB[83] and gyrB[84] genes to determine different species of mycobacteria, including *M. tb*. In addition, recent reports from the developing countries describe the use of real-time PCR for species identification of mycobacteria.[85-88]

Diagnostic Tests for Drug-Resistance of MTB

Even as efforts to devise improved diagnostic tests for TB are ongoing, there has been an alarming increase in the incidence of Multidrug-Resistant TB (MDR-TB) and Extensively Drug-Resistant Tuberculosis (XDR-TB) in several parts of the world.[89-91] MDR-TB is defined as resistance to both INH and rifampicin and XDR-TB is defined as MDR-TB with additional resistance to any fluoroquinolone and at least one of the three injectable Second-Line Drugs (SLDs)—capreomycin, kanamycin and amikacin. As per the WHO estimates, almost 25% of the 5 million cases of MDR-TB that emerged globally in 2006, were from India. Recent studies have reported both MDR-TB and XDR-TB in India.[92-94]

Conventional diagnosis of DR-TB by the proportion method, absolute concentration method or the resistance ratio method takes several weeks even with the rapid-culture (BACTEC 460, MB/BacT, MGIT) based methods since the primary isolation and culture of *M. tb* from the clinical specimen is followed by susceptibility testing in cultures. During this time, transmission of resistant bacteria continues and patients are treated with inappropriate regimens, potentially amplifying resistance.

Rifampicin (Rif) is the key drug in the first-line chemotherapy of TB and it is estimated that over 90% of the Rif-resistant strains are also INH-resistant. Two commercial assays for rapid detection of drug resistance in *M. tb* have become available: The Line Probe Assay (LiPA) (INNO-LiPA RifTB Assay, Innogenetics) for the detection of resistance to rifampicin and the GenoType MTBDRPlus (Hain Lifescience) for simultaneous detection of rifampicin and isoniazid resistance. The basis of both assays is reverse solid phase hybridization. The line probe assays involve extraction of DNA from *M. tb* isolates, either from cultures or directly from clinical specimens, followed by PCR-amplification of the resistance-determining region of the gene in question using biotinylated primers. The PCR products are hybridized with specific oligonucleotide probes that are immobilized on a strip. The captured hybrids are detected by colorimetric development. The mutations are identified by lack of hybridization of the amplified PCR products to wild type probes as well as hybridization to specific probes for most commonly occurring mutations.

Results from systematic reviews and meta-analysis commissioned by WHO in 2008[95] showed that line probe assays are highly sensitive (>97%) and specific (>99%) for the detection of rifampicin resistance, either alone or in combination with INH. Moreover, the assay performance was maintained even when sputum specimens were used. Since these assays require processing of sputum specimens, use of BSL3 facilities is recommended for using these tests. Moreover, reagents for these assays require refrigeration and/or freezing, which translates into regular power supply, molecular grade water and enzyme (Taq polymerase) and several different equipment (thermal cycler, shaker platform, water bath, heating block, sonicator, hybridization chambers, etc.). Clearly, these tests require significant infrastructure and training and will be difficult to implement except in the few sophisticated labs in developing countries.

A new nucleic acid amplification-based diagnostic technology called Cepheid Gene Xpert® System for simultaneous detection of *M. tb* and rifampicin resistance has just been reported.[96] The Cepheid system is an integrated diagnostic system that performs sample processing and real-time PCR analysis test in a single hands-free two-hour step. The assay is designed to perform a hemi-nested molecular beacon assay, which uses six molecular beacons to amplify a sequence of the rpoB gene specific to the *M. tb* complex organisms and probe for mutations in the RRDR (Rifampicin Resistance Determining Region) of the rpoB gene. This is an 81bp long region in the rpoB gene, mutations in which occur in 95 to 98% of the rifampicin-resistant *M. tb*. Fluorescent dyes and quenchers that allow multiplexing of the different molecular beacons within the same reaction make this system extremely sensitive for the detection of *M. tb*. The sensitivity of the assay is similar to the culture-based diagnostics making it an attractive new diagnostic system for rapid detection of drug resistance. However, currently instrumentation and reagent costs are unacceptably high, and validation in true third-world settings is still to be performed.

Another technology being developed for the detection of *M. tb* drug resistance is based on using bacteriophages. There is currently only one commercial manufacturer of phage-based tests on the market, Biotec Laboratories Limited (Ipswich, Suffolk, UK), which produces the FASTPlaque™ assay. Their first generation test for the detection of rifampicin resistance, FASTPlaque-RIF™ or FASTPlaque-MDRi™, was used only with *M. tb* isolates.

This has now been replaced by the FASTPlaque-Response™, which can be used directly on patient specimens. The basic principle underlying these drug-sensitivity tests is that since the mycobacteriophage D29 replicates only in viable *M. tb*, the inclusion of drugs to which the *M. tb* is sensitive results in abrogation of phage replication.

The other phage-based assay for detection of MDR-TB strains is based on the Luciferase Reporter Phages (LRP), which emit light after infection of, and amplification in *M. tb*.[97-99] The LRP assay is an in-house format and earlier efforts were made to develop a commercial semi-automated version (Sequella Inc, Rockville, MD, USA) of this assay but now the company has discontinued development.[100] Compared to the conventional tests the sensitivity of detection of rifampicin resistance in LRP assay has ranges from 92 to 100% while the specificity is reported to range from 89 to 100%. All studies that have evaluated drug-resistance with the LRP-based assay have used bacteria that were cultured from the sputum specimens and its performance with direct evaluation of sputum bacteria is not known.[97-99]

Recently, a meta-analysis of commercial FASTPlaque™ assays, LRP assays and in-house phage amplification tests based on findings of 31 studies (with 3,085 specimens) was performed. For the detection of rifampicin resistance, commercial phage amplification assays yielded more variable ranges of sensitivity (range 81 to 100%) and specificity (range 73 to 100%) compared to in-house amplification assays (sensitivity range 88 to 100%, specificity range 84 to 100%). LRP evaluations yielded the most consistent estimates of diagnostic accuracy, with seven of eight studies reporting 100% sensitivity and four of eight reporting 100% specificity. The major drawback of the commercial assay included high rate of contaminated and indeterminate results particularly during direct detection of Rif resistance from patient specimens. Thus, phage-based assays need further development to maximize interpretable results and reduce technical failures and as per the recommendations of WHO Expert Group, there is insufficient evidence to recommend the use of phage based assays for rapid screening of patients suspected of having MDR-TB.[101]

Recently, microarray technology has also been evaluated for drug resistance detection in *M. tb*.[102-104] The microarrays or DNA biochips allow simultaneous detection of multiple mutations. A low-density oligonucleotide chip has been reported to detect mutations associated with INH, RIF, SM, KM, and EMB with sensitivities of 69%, 93%, 86%, 80% and 85%, respectively.[105] Gel-based biochips have been used for epidemiological studies of drug resistance on a large scale in Kyrgyz Republic.[106] The latest generation of TB biochips for analysis of second line fluoroquinolone antibiotics resistance along with rifampicin/isoniazid susceptibility biochip is the first in the world to be certified by a national regulatory agency, Ministry of Public Health of Russian Federation for clinical application.[106] However, the usefulness of molecular tests, including biochips is limited by the fact that not all drug-resistant isolates have mutations in the hot spots of genes associated with drug resistance. These strains still require phenotype based assays for detection. Secondly, the molecular tests are unable to detect minor populations of drug resistant organisms in primary culture from clinical samples.[105]

Interferon Gamma Release Assays

Besides the sensitivity and specificity issues discussed earlier, a major limitation of the TST is that the administration and reading of the test is subject to inter-operator variability and repeated visit of patients to the clinic are required for the measurement of induration and erythema. Significant advances in mycobacterial genomics and cellular research in last decade has resulted in the development of two new commercial blood tests, the enzyme-linked immunospot assay (ELISpot) (T-SPOT.TB, Oxford Immunotec, Oxford, UK) and the Enzyme-Linked Immunosorbent Assay (ELISA) (QuantiFERON-TB Gold;QFT-G/ QuantiFERON-TB Gold In-Tube; QFT-GIT, Cellestis, Carnegie, Australia). These tests, which are collectively known as IGRAs, detect LTBI by measuring Interferon (IFN)-γ release in response to overlapping peptides of two proteins, ESAT6 and CFP10, that are present in *M. tb*, but not Bacille Calmette-Guérin (BCG) vaccine and most nontuberculous mycobacteria. This is done through the enumeration of IFN-γ-secreting T cells (ELISpot) or by measurement of IFN-γ concentration by ELISA (QFT-G/ QFT-GIT).The QFT-GIT assay also includes peptides of another *M. tb* protein, called TB7.7 in addition to the peptides of ESAT6 and CFP10.[107] These tests have European CE Mark and US FDA approval.

A comprehensive review on utility of the IGRAs in diagnosis of clinical and latent TB has been published recently.[108] The ability of these antigens to elicit γIFN from PBMCs of active TB patients has been evaluated by many different labs and sensitivities ranging from almost 80 to 90% have been reported.[108] The similar sensitivity in smear-positive or smear-negative TB patients and in pulmonary and extrapulmonary TB and the ability to obtain results within two to three days as opposed to waiting for weeks for AFB cultures to become positive are advantages of these tests.[108-110] It is important to recognize that IGRAs are tests of infection, rather than disease, and cannot distinguish between LTBI and active TB, but since infection with *M. tb* is a prerequisite for active TB, a negative test result might in theory rapidly exclude TB from the differential diagnosis.

The ability of IGRAs to identify false positive responses that are detected by PPD is an asset to TB control in developed nations, in terms of avoiding unnecessary preventive therapy. For these reasons, IGRAs are becoming a part of the algorithm for identifying *M. tb* infected patients in non-endemic countries and is being considered for initial and serial testing of persons with increased risk for LTBI (recent immigrants, injection drug users, prisoners and jail personnel) and for individuals who may be at high risk for exposure (health care workers, military personnel). Recent meta-analysis based on the studies investigating sensitivity and specificity of the commercial T-Spot. TB and QFT-GIT assay as compared to TST among definitely confirmed TB cases concluded that the newest commercial IGRAs are superior, in comparison with the TST, for detecting confirmed active TB disease in developed countries.[111] Recently, guidelines and recommendations for the use of the QFT tests for detection of LTBI have been provided by the CDC.[112]

There is no gold standard for the detection of LTBI, which makes it difficult to determine the sensitivity and specificity of these tests in identification of latent infection, however, the major advantage of IGRAs is their improved specificity in detecting *M. tb* infection in subjects who are BCG vaccinated. In several studies of contacts of infectious TB patients, an excellent correlation between the degree of exposure to *M. tb* and the extent of γIFN responses or presence of T cells making γIFN in response to these antigens was observed and most studies provide estimates of improved sensitivity and specificity as compared to the PPD test.[113-116] Although IGRAs have impacted the diagnosis of LTBI in low burden countries, their value in high-burden settings is limited where large proportions of the subjects have LTBI and preventive therapy is not feasible or provided.[26,114] Moreover, increasing proportions of TB patients are coinfected with HIV and tests based on cellular immune responses have limitations in individuals with compromised immunity. For these reasons, the impact of these new tests on global TB control is likely to be insignificant.

Antibody-Detection Based Diagnosis of TB

Efforts to devise a serodiagnostic test for TB have been made for decades and a vast body of confusing and contradictory literature is available and over 20 serodiagnostic assays are currently marketed in developing countries. Most of the tests are based on the 38 kDa antigen of *M. tb* or LAM and/or other undisclosed antigens. In recent years, the WHO Special Program for Research and Training in Tropical Diseases (TDR) commissioned two systematic reviews on serological tests, which have performed a careful and thorough meta-analysis of the accuracy of these tests for the diagnosis of pulmonary and extrapulmonary TB. A list of the commercial tests evaluated is available in the published reviews.[117,118] These reviews concluded that all the tests provided highly variable sensitivities and specificities and none of them could be used for reliable diagnosis of TB, either in non-HIV or HIV-infected patients or in pediatric patients.

In addition to having high sensitivity and specificity, for any new diagnostic markers to have any impact on the TB epidemic, and to be integrated into the already overburdened TB control programs in the developing countries, they must be rapid, low-cost, operationally simple requiring minimal laboratory infrastructure and personnel training, robust and stable to withstand the poor storage conditions in these countries, and be amenable to large-scale production. For these reasons, despite the dismal history, two factors have continued to spur interest and effort from the academic community in devising serodiagnostic test for TB. First, the availability of the new tools of genomics and proteomics has accelerated the pace at which antigens of *M. tb* can be identified, cloned and tested. Also, once the optimal antigens/epitopes are identified, immunoassays can be adapted to easy, rapid format, inexpensive Point-of-Care (POC) tests that can be integrated into the TB control programs in developing countries without the requirement for investment in establishment and the maintenance of sophisticated laboratory infrastructure. Several new antigens have been reported in recent years.[119-129]

In 2008, the WHO/TDR commissioned a review of the immunodiagnostic potential of all new protein and non-protein antigens reported from different laboratories since 1990. These meta-analysis revealed that while no single antigen could detect all sputum smear-positive TB patients, one recombinant antigen, the malate synthase (Rv 1836c) provided the highest sensitivity (73%; CI 58–85) of all antigens identified so far.[130] These analysis also showed that compared to single antigens, multiple antigens provided improved sensitivities and the combination of a TB protein called DPEP plus a multiepitope protein TbF6 provided similar sensitivity as the malate synthase.[130] Other studies have shown that malate synthase and MPT51 (Rv 3803c) together provide a sensitivity of more than 80% in both HIV+ and non-HIV sputum smear-positive TB patients.[131] Importantly, the specificities obtained with these purified recombinant proteins are high.[130]

An interesting and important advancement in devising serodiagnosis for TB has been the demonstration that epitope mapping of carefully selected, highly immunogenic proteins of *M. tb* can potentially yield peptides that may be used to devise diagnostic tests for TB.[132,133] The use of peptide microarrays can potentially enable rapid screening of thousands of peptides representing the immunologically relevant proteins.[134,135] Although no peptide-based diagnostic test for TB is currently available, it is likely that diagnostic tests based on immunodominant peptides derived from *M. tb*–specific proteins that are highly immunogenic in TB patients will become available in the next few years.

The Optimal TB Test

It is important to appreciate the differences between the developed and developing countries in regards to TB. The former countries have a low-burden of TB, possess adequate resources to subject TB suspects to intensive expensive investigations (sophisticated microscopy, IGRAs, cultures, nucleic acid detection based tests), which result in earlier and accurate diagnosis, and to carefully monitor not only treatment of the patients, but also conduct contact investigations and identify and treat contacts who have LTBI. The goal in these settings is to eliminate TB. Unfortunately, the diagnostic tests that are used in mycobacteriology labs in the industrialized world as well as the resources required for monitoring treatment are too expensive and technically difficult for routine use in resource-limited countries. The patient burden is enormous; accuracy of microscopy is limited and facilities for culture-confirmation are rarely available.

Some laboratories in the developing world are beginning to introduce automated culture systems, nucleic acid probes, etc. Their integration into routine patient care will likely not be possible. For these reasons, these countries focus on control of TB, and maximum effort and resources are directed towards detection and treatment of the highly infectious cases, which seek medical intervention; by the time this passive case-finding identifies a patient, considerable transmission has already occurred. Even affordable new diagnostic tests that can replace and improve upon microscopy, and be integrated into routine patient care would impact TB control in these countries. Unfortunately, the few diagnostic tests that have been devised so far or are in development continue to be useful primarily for the high end of the TB market.

The ideal diagnostic marker for TB would be a universal marker that can be the following:

a. Replace and improve upon sputum microscopy
b. Identify patients with extrapulmonary TB, which can occur at different sites (TB meningitis, skeletal TB, genitourinary TB, gastrointestinal TB, TB lymphadenitis) many of which are not accessible to microscopy[8,136,137]
c. Identify HIV-infected TB patients, in whom TB progresses rapidly and fatally, but the low bacterial burden in the sputum makes detection of bacteria or bacterial molecules difficult, and the immune dysfunction preclude use of cellular immune-based diagnostic assays[4,25]
d. Diagnose pediatric TB patients who rarely produce sputum and are currently diagnosed based on epidemiologic, clinical and radiological suspicion rather than microbiological confirmation[138,139]
e. Because *M. tb* has a long generation time and the period from infection to clinical disease can be several months, the ideal markers would identify a potential TB patient during this window of time and so must differentiate between an incipient subclinical infection (where *M. tb* is replicating actively and the infection is progressing to clinical TB) and a truly latent infection that is unlikely to result in disease

In the absence of a single universal marker, a set of new diagnostic tests may be able to fulfill these criteria. Not only must the new diagnostic tests detect the myriad forms and stages of TB with high sensitivity, they must be highly specific. Thus, although almost 84% of the *M. tb* genome encodes proteins that are cross-reactive with other mycobacteria or other prokaryotes,[140] the diagnostic markers must be able to distinguish between infection with *M. tb* and infection or exposure to other bacteria and mycobacteria. In addition to having high sensitivity and specificity, for any new diagnostic markers to have any impact on the TB epidemic and to be integrated into the already overburdened TB control programs in the developing countries they must be rapid, low-cost, operationally simple requiring minimal laboratory infrastructure and personnel training, robust and stable to withstand the poor storage conditions in these countries and be amenable to large-scale production.

Management of Tuberculosis*

D Behera

CHEMOTHERAPY OF TUBERCULOSIS

The modern era of tuberculosis treatment—short-course chemotherapy—began with the first East-African/BMRC study in the early 70s and subsequent studies at different parts of the world,[1] which demonstrated that the addition of rifampin to isoniazid and streptomycin allowed a dramatic curtailment from 18 months to 6 months in the duration of drug therapy required to elicit cures in 95% or more of patients, which is considered as the gold standard of the efficacy of any chemotherapy program. Subsequently, a number of clinical trials all over the world continued in a wide variety of populations and health service conditions, which have confirmed that the duration of treatment can be reduced to 6 to 9 months from the earlier 12 to 18 months with the use of suitable combinations of antitubercular drugs.[2-12] Since then, short course chemotherapy is now widely accepted as the treatment of choice for pulmonary tuberculosis. From the results of clinical trials and of complimentary laboratory studies, the mechanisms of action of the main antitubercular drugs and their contributions to regimens are becoming increasingly well understood.

The antituberculosis drugs vary in (i) their bactericidal action, defined as their ability to kill large numbers of actively metabolizing bacilli rapidly, (ii) their sterilizing action, defined as their capacity to kill special populations of slowly or intermittently metabolizing semidormant bacilli: The so called "persisters", (iii) their ability to prevent the emergence of acquired resistance by suppressing drug-resistant mutants present in all large bacterial populations, and (iv) their suitability for intermittent use.[13]

Prevention of Drug-Resistance

Drugs can be graded according to their activity in preventing the emergence of resistance to a second drug, usually isoniazid. Even populations of tubercle bacilli, which are not exposed to antitubercular drugs, contain small proportions of drug-resistant mutants. The proportion of such mutants in wild strains is 1 in 10^5 to 10^6 for streptomycin, isoniazid and ethambutol and 1 in 10^7 for rifampicin. If inadequate drug combinations are used, these mutants are likely to replace the killed susceptible bacilli and give rise to drug-resistant disease. The effectiveness of drugs in preventing the emergence of acquired resistance depends upon the extent to which they can inhibit bacilli continuously, whatever their rate of metabolism, even if there is some irregularity in taking drugs. Isoniazid and rifampicin are the most effective at preventing the emergence of resistance to other drugs, and streptomycin and ethambutol are only slightly less. Pyrazinamide is less effective, and PAS and thiacetazone are the least effective. Activity of a drug is assessed from the results of clinical studies of the treatment of smear positive pulmonary tuberculosis in which the drug concerned is given in a 2-drug combination with isoniazid. Drug gradings are based on the proportion of patients who failed during treatment with the emergence of isoniazid-resistance. This proportion is about 0.5% for rifampicin (high activity) and 13 to 15% for thiacetazone (low activity).

Early Bactericidal Activity

Jindani examined the early bactericidal activity of drugs and others[14] in patients with pulmonary tuberculosis treated for 14 days with single drugs or with various drug combinations, followed by conventional regimens. Most of the antitubercular drugs (INH, rifampin, streptomycin, pyrazinamide) have bactericidal activity. Of them isoniazid kills the largest number of bacilli early during the first two days of chemotherapy in a rate of 0.72 $\log_{10}$ cfu/ml/day when given alone and the kill of other drugs is increased considerably by 0.36 $\log_{10}$ cfu/ml/day when isoniazid is added to them in treatment. Next in order of bactericidal activity are ethambutol and rifampin with rates of kill of 0.25 $\log_{10}$ cfu/ml/day and 0.19 $\log_{10}$ cfu/ml/day, respectively. They add little or nothing to the activity of second drugs. Streptomycin, thiacetazone, and pyrazinamide are just bactericidal with rates of kill of 0.09 to 0.04 $\log_{10}$ cfu/ml/day.

Sterilizing Action

Sterilizing activity is the ability to kill all or virtually all of the bacilli in the lesions as rapidly as possible. As the speed of killing gets progressively slower during chemotherapy, sterilizing activity measures the speed with which the last few viable bacilli are killed. This activity is assessed in man by (i) proportion of sputum cultures that are negative at two months, or round about that time, after the start of treatment, and (ii) the proportion of relapses that occur after chemotherapy has been stopped. The sterilizing activity of a drug indicates its suitability for incorporation in short course regimens. The two drugs with the greatest sterilizing activity are rifampicin and pyrazinamide. Isoniazid is less active, taking longer time to sterilize lesions. Though less active than isoniazid, addition of streptomycin or thiacetazone to a regimen probably increases its sterilizing activity to a very small extent.[15] Ethambutol virtually has no sterilizing activity.

Mitchison in 1979[16] had suggested a special populations hypothesis and subsequently an extension of this hypothesis explaining the bactericidal and sterilizing activities of various drugs. This is shown in Figure 42.1.

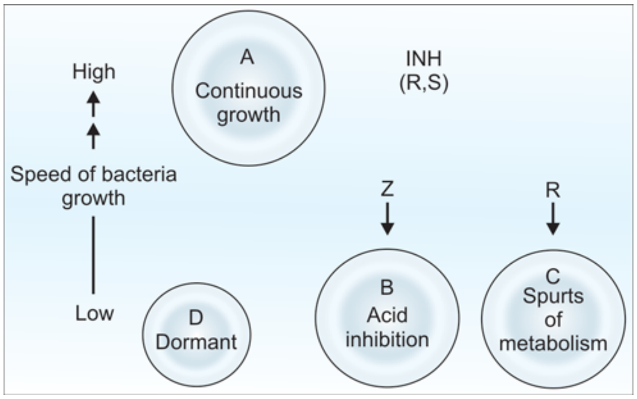

Fig. 42.1: Special bacterial population hypothesis by Mitchison R-rifampin, S-streptomycin, Z-pyrazinamide

The majority of the tubercle bacilli in the lesions at the start of treatment are growing more or less rapidly (*population A*). Isoniazid kills them during the first few days of chemotherapy. Other drugs contribute to the bactericidal activity, only if INH is not included or the bacilli are resistant to it. Other bacilli are almost dormant and, therefore antitubercular drugs, including INH kill them only slowly. Some of these semidormant bacilli are in an acid environment, perhaps inhibited by acidity or by poor oxygen supply because of low pO_2 (inside macrophages or in areas of inflammation) and are best killed by pyrazinamide, because it is active only at a pH of about 5.5 or less (*population B*). Other semidormant bacilli have occasional spurts of active metabolism, lasting perhaps for few hours (*population C*) and these are killed most efficiently by rifampicin because its bactericidal action starts very quickly during the spurts of metabolism, before isoniazid has a chance to start killing. The organisms may be in neutral or an acid environment, so that there is some overlap between populations B and C. Finally, there is a completely dormant population of bacilli (*population D*), which is unaffected by any drug. Thus, early bactericidal activity kills population A, while populations B and C are killed by drugs with high sterilizing activity throughout the entire period of chemotherapy. However, subsequent observations proved that these assumptions are not entirely correct, and, therefore, an "extended special population theory" was proposed (Fig. 42.2). According to this hypothesis, most of the bacilli in the lesions at the start of treatment exist in extracellular sites, including the areas of caseation where they are not closely surrounded by inflammatory cells. These bacilli (corresponding to population A in Fig. 42.1) are in a mildly acid environment (6.5–7.0) and most are growing fairly rapidly. These population of bacilli are killed rapidly by INH actively, streptomycin is weakly bactericidal because of overall acidic pH, and pyrazinamide is not bactericidal because the pH is not sufficiently acidic.

As further inflammatory reaction proceeds, the pH falls and the organisms are partially inhibited (population B and C of Fig. 42.1). Pyrazinamide and rifampicin are now more bactericidal than INH and streptomycin is completely inactive. There is a steady transfer of bacilli from population A to population B in open cavities that contains majority of the bacilli. After several weeks of

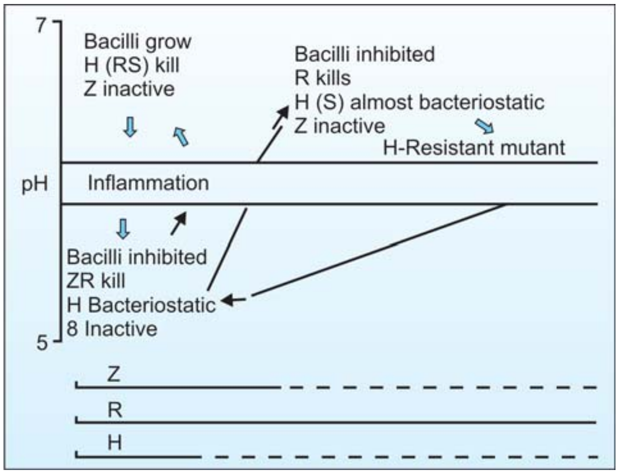

Fig. 42.2: Role of pH and inflammation in modifying the growth of *M. tuberculosis*. The circulation of periods of rapid killing by ZR and H is indicated in the lower part

TABLE 42.1: Grading of activities of antituberculosis drugs

Extent of activity	*Prevention of resistance*	*Early bactericidal*	*Sterilizing*
High	Isoniazid	Isoniazid	Rifampicin
	Rifampicin		Pyrazinamide
		Ethambutol	
	Ethambutol	Rifampicin	Isoniazid
	Streptomycin		
		Streptomycin	Streptomycin
	Pyrazinamide	Pyrazinamide	Thiacetazone
Low	Thiacetazone	Thiacetazone	Ethambutol

treatment, the inflammation starts dying down, and the pH reverts towards the 6.5 to 7.0 ranges. The bacilli, corresponding to population C, are persisters and are relatively refractory to chemotherapy. Rifampicin has the greatest activity against them, and INH and streptomycin are slow killers. Because of higher pH, pyrazinamide is inactive and therefore, the drug has no sterilizing activity after the first-two months of short course chemotherapy.[17] However, if the bacilli again start to multiply, because of any reason (i.e. isoniazid resistance) local inflammation begins again, the pH falls and the situation is repeated with the necessity of pyrazinamide to kill the bacilli. Thus in multidrug short course regimens, the main killing activity of pyrazinamide occurs during the first few weeks of chemotherapy, while killing by rifampicin continues throughout treatment and isoniazid has its main activity during the first few days.

Suitability for Intermittent Use

Isoniazid, rifampicin, pyrazinamide, streptomycin and ethambutol are all effective when given twice or thrice a week. Thiacetazone is less effective when given intermittently than when given daily. From the above discussion, it is quite clear that the three functions of early bactericidal activity, sterilizing activity, and ability to prevent drug resistance are unrelated. In the combinations, in which they are given, are effective because one or the other drug is having different grade of above activities. For example, while rifampicin has early bactericidal activity (rapidity of killing), in fact it is weakly bactericidal compared to isoniazid. Similarly, the importance of ethambutol in short course chemotherapy lies not because it is a bactericidal or sterilizing drug, but it plays part in the prevention of failure as a result of initial drug resistance. The relative activities of the main antitubercular drugs in each of the above three functions are summarized in Table 42.1.

The existence of dormant tubercle bacilli or the persisters for long periods after chemotherapy was shown by McCune et al nearly 40 years ago, soon after the discovery of isoniazid, and is known as the "Cornell Model".[18] These studies supplemented by other experimental studies formed the basis of short course chemotherapy.[19] The success of short course chemotherapy regimens containing rifampicin showed that the drug could kill tubercle bacilli even with the shorter periods of contact, whereas other powerful drugs like isoniazid require about one generation time (24 hours). Based on these explanations and other clinical trials, the established short course chemotherapy became widely acceptable. Unfortunately, the emergence of new molecular biology techniques like Polymerase Chain Reaction (PCR), Single-Strand Conformation Polymorphism (SSCP) analysis, and Restriction Fragment Length Polymorphism (RFPL) have shown persistence of mycobacterial DNA in the animal tissues as well as in human material after discontinuation of therapy.[20,21] The relevance of these reports in the context of clinical practice is not clear and whether these may be indicators of reemergence of tuberculosis are yet to be answered.

With the available information, many countries have developed guidelines for the treatment of tuberculosis.[22-33] The basic principle is the same, i.e. short course chemotherapy of six months duration.

A number of National and International guidelines for the treatment of pulmonary tuberculosis are available. They are:

The Committee on treatment of the International Union Against Tuberculosis and Lung Diseases, at its meeting in Singapore in November 1986 has made specific recommendations on antituberculosis regimens and drug dosages to be used in the treatment of adults and children with active pulmonary or extrapulmonary tuberculosis requiring chemotherapy, which is given in Table 42.2.[23]

The committee has also recommended the use of drugs in various other situations like the presence of complicating diseases, the treatment of drug resistant cases, and management of patients who develops toxic reactions to a drug, but otherwise treatment should be continued. These will be discussed in brief. The dosages of the drugs are given in Table 42.3. The dosages are appropriate for all forms of tuberculosis, including meningitis and miliary tuberculosis and for children, as well as adults. In the past, a higher dose was used for children, especially for isoniazid, which should be avoided which otherwise leads to needless adverse effects.

The World Health Organization has published guidelines for the treatment of tuberculosis for national programs.[34] In order to standardize short course chemotherapy in national tuberculosis programs, case definitions are required. The main purposes of these case definitions are for the proper patient registration and case notification, to evaluate the trend in the proportions of new smear-positive cases and smear-positive relapse and other treatment cases, to allocate cases to standardized treatment categories, and for cohort analysis. There are four determinants of case definition—the site of tuberculosis, severity of the disease, bacteriology and the history of previous treatment. WHO recommends the following definitions.

TABLE 42.2: Recommendations of IUATLD regimens of chemotherapy

A. *Recommended standard six-month regimen* 2hrz/4hr
Variants of standard six-month regimen
- I. *When fully supervised intermittent chemotherapy can be organized*
  - 2 $HRZ/4H_3R_3$
  - 2 $HRZ/4H_2R_2$
  - 2 $E_3H_3R_3Z_3/4H_3R_3$
  - 2 $S_3H_3R_3Z_3/4H_3R_3$
- II. *When there is a high level of initial resistance*
  - 2 EHRZ/4HR

  - 2 SHP/10HP
  - 2 $SHT/10S_2H_2$
  - 2 $SHP/10S_2H_2$

S: Streptomycin; H: Isoniazid; R: Rifampicin; Z: Pyrazinamide; E: Ethambutol; T: Thiacetazone; P-PAS. The numbers indicate duration in months. The subscript numbers indicate the frequency per week.

An active case of tuberculosis refers to symptomatic disease due to infection with *Mycobacterium tuberculosis* complex.

Site of Tubercular Disease (Pulmonary or Extrapulmonary)

In general, recommended treatment regimens are similar for both pulmonary and extrapulmonary tuberculosis and are the same irrespective of the site of disease, although some authorities recommend a prolonged continuation phase for tubercular meningitis. Pulmonary tuberculosis refers to disease involving the pulmonary parenchyma. Intrathoracic tuberculous lymphadenitis

and pleural effusions without radiographic parenchymal involvement are taken as extrapulmonary tuberculosis. A patient with both pulmonary and extrapulmonary tuberculosis constitutes a case of pulmonary tuberculosis. The case definition of an extrapulmonary case with several sites affected depends upon the site representing the most severe form of the disease.

Severity of Disease

Bacillary load, extent of disease and anatomical site involvement are taken into account in defining the severity of the disease. Involvement of an anatomical site results in classification as severe disease if there is either a significant acute threat to life as in pericardial tuberculosis, or a risk of subsequent severe sequel with handicap as in spinal tuberculosis or both as in tuberculous meningitis. Thus, the following forms of extrapulmonary tuberculosis are classified as severe: Meningitis, miliary, pericarditis, peritonitis, and bilateral or extensive pleural effusion, spinal, intestinal and genitourinary. Other forms of extrapulmonary tuberculosis like lymphadenitis, unilateral pleural effusion, and bone excluding spine, peripheral joint, and skin are classified as less severe.

Bacteriology (Result of Sputum Smear)

It is very important to define the smear result in pulmonary cases because smear-positive cases are the most infectious and they have an increased mortality and the positive cases are the only ones for which bacteriological monitoring of cure is possible. A smear-positive pulmonary tuberculosis is one if (i) at least two sputum specimens are positive for acid fast bacilli by microscopy; or (ii) if at least there is one sputum specimen is positive for acid fast bacilli by microscopy and radiographic abnormalities consistent with pulmonary tuberculosis and a decision by a physician to treat with a full curative course of antituberculous chemotherapy; or (iii) a patient with at least one specimen positive for acid fast bacilli by microscopy, and which is culture positive for *M. tuberculosis*. Under program conditions with microscopy services available, pulmonary tuberculosis smear-positive cases represent about 65% of the total pulmonary tuberculosis cases in adults and 50% or more of all tuberculosis cases when diagnostic criteria are properly applied. This proportion may be **lower in high in populations (author to kindly verify)** with a high incidence of Human Immunodeficiency Virus (HIV) infection. A smear-negative pulmonary tuber-culosis is one (i) if two sets of at least two sputum specimens negative for acid fast bacilli on microscopy examined at least two weeks apart; and (ii) radiographic abnormalities consistent with pulmonary tuberculosis and a lack of clinical response despite one week of a broad spectrum antibiotic; and (iii) a decision by a physician to treat with a full curative course of antitubercular drugs. The category also includes patients who are severely ill; and at least two sputum specimens negative for acid-fast bacilli by microscopy; and radiographic abnormalities consistent with extensive pulmonary tuberculosis like interstitial or miliary form of the disease; and a decision by a physician to treat with a full curative course of antitubercular chemotherapy. The other group of patients that comes under this category are those whose initial sputum were negative, who had sputum sent for culture initially, and whose subsequent sputum culture results are positive. Thus, in the absence of culture, standard chest radiography is necessary to document cases of smear-negative pulmonary tuberculosis. Fluoroscopy examination results are not acceptable as documented evidence of pulmonary tuberculosis.

History of Previous Treatment

By this information, a case is defined whether or a patient had previous antitubercular treatment or not. This is important because by this case definition patients are identified who are at increased risk of acquired drug resistance and the prescription of appropriate treatment; and for epidemiological monitoring. Accordingly the following five different categories of cases can be identified:

New Case

A patient who has never had treatment for tuberculosis or who has taken antitubercular drugs for less than four weeks.

Relapse

A patient who has been declared cured of any form of tuberculosis in the past by a physician, after one full course of chemotherapy, and has become sputum smear-positive.

Treatment Failure

A patient who, while on treatment, remained or became again smear-positive five months or later after commencing treatment. It is also a patient who was initially smear-negative before starting treatment and became smear-positive after the second month of treatment.

Treatment after Interruption (TAI) or Return after Default

A patient who interrupt treatment for two months or more, and returns to the health service with smear-positive sputum or sometimes smear-negative, but still with active disease clinically and radiologically.

Chronic Case

A patient who remained or became again smear-positive after completing a fully supervised retreatment regimen.

Although smear-negative and extrapulmonary cases may also be treatment failures, relapses, or chronic cases, this is rare. The importance of case definitions as above is important for registration, notification and to define treatment categories.

RATIONALE FOR RECOMMENDED TREATMENT REGIMENS

For new cases, treatment regimens have an initial or intensive phase for two months and a continuation phase lasting for four to six months. During the initial intensive phase of therapy four, drugs are administered wherein a rapid killing of bacilli takes place. Infectious patients become noninfectious within about two weeks. Symptoms improve. The vast majority of cases with sputum smear-positive tuberculosis become sputum negative within two months. In the continuation phase fewer drugs, usually two, are required, but for a longer period of four to six months. The sterilizing effect of the drugs eliminates remaining bacilli and prevent relapse. In smear-positive cases, there is a risk of selecting resistant bacilli as these patients harbor and excrete a large number of bacilli. However, short course chemotherapy consisting of four drugs initially and two drugs subsequently, reduce this risk of selecting resistant bacilli. These drugs are practically as effective in patients with initial resistant organisms as in those with sensitive organisms. In patients with smear-negative pulmonary tuberculosis and extrapulmonary tuberculosis, there is little risk of selection as these patients carry only a small bacillary load. Short-course chemotherapy regimens with three drugs initially with two drugs during the continuation phase are sufficient.

In retreatment cases there is a chance of drug resistance. They are more likely than new patients to harbor and excrete bacilli resistant to at least isoniazid. This regimen consists initially of five drugs, with three drugs in the continuation phase. The patient receives at least two drugs in the initial phase, which are still effective. This reduces further selection of resistant organisms.

From the public health perspective the priority of treatment is given to the infectious cases. Because of resource constrains, treatment is rationalized by resource allocation to priorities tuberculosis treatment categories according to the cost-effectiveness of the treatment of each category. Accordingly, treatment categories are ranked from I (highest priority) to IV (lowest priority). Recommended regimens for different categories may differ from country to country as per the National Tuberculosis Program, which in turn depends on the budget, health coverage by Primary Health Care services, and qualification of health staff at the peripheral level. The WHO recommendation of treatment regimens according to categories is shown in Table 42.4. Category IV has since been defined clearly.

Category I

In this group, smear-positive pulmonary tuberculosis gets the highest priority for treatment. Urgent treatment is also required for patients with the other forms of disease because of associated morbidity and mortality. When the patient completes the initial phase of treatment and the sputum is smear-negative, the continuation phase is started. However, if the smear is still positive at eight weeks, the initial phase of therapy should be extended for another two to four weeks. The patient is then started with the continuation phase regardless of the result of sputum result. In populations with low probability of initial resistance three drugs (R, H, Z) in the intensive phase is sufficient. Some experts recom-mend a seven month continuation phase with daily isoniazid and rifampicin (7 HR) for category I patients with TB meningitis, miliary tuberculosis, spinal tuberculosis with neurological signs. In the continuation phase, an alternative treatment regimen like six months of isoniazid and thiacetazone can be given daily. In proven or suspected cases of HIV infection (young adults from countries with a high incidence of HIV infection), ethambutol should be used in place of thiacetazone.

Category II

The treatment priority in this category is again highest. These patients are likely to have isoniazid-resistant and/or streptomycin-resistant disease. If possible, a pretreatment sputum specimen should be obtained for

TABLE 42.4: Possible alternative treatment regimens for each treatment category[33]

Treatment category	*Description of patients*	*Alternative treatment regimens*	
		Initial phase (daily or 3/week)	*Continuation phase*
I	New smear-positive TB New smear-negative TB with extensive parenchymal involvement; new cases of severe forms of extrapulmonary tuberculosis (see above))	2 EHRZ (SHRZ) 2 EHRZ (SHRZ) 2 EHRZ (SHRZ)	6 HE/6HT 4 HR 4 H_3R_3
II	Sputum-smear positive: Relapse; Treatment failure; Treatment after interruption	2 SHRZE/1 HRZE 2 SHRZE/ 1 HRZE	5 $H_3R_3E_3$ 5 HRE
III	New smear-negative TB (Other than in Category I) new less severe forms of extrapulmonary TB	2 HRZ 2 HRZ 2 HRZ	6 HE 4 HR 4 H_3R_3
IV	Chronic cases (still sputum positive after supervised retreatment)	Second-line drugs are to be used in specialized centers.	

culture and susceptibility testing to H, R, E and S. These patients are also at increased risk of developing multidrug-resistant disease and should receive fully supervised treatment for at least three months. If the sputum is still positive at the end of three months, they should continue to receive supervised therapy till sputum conversion is documented or till they are classified as a chronic case. When the patient is sputum-negative at the end of 12 weeks, the continuation phase is started.

If the pretreatment studies showed resistance to isoniazid or rifampicin alone, the patient should start the continuation phase under close supervision, preferably in a referral hospital. In this situation, sputum conversion is likely to occur, provided that all the doses of drugs are taken till the end.

If the pretreatment report showed resistance to both isoniazid and rifampicin, or resistance to both these drugs is found in patient who remains sputum-positive at the end of the initial phase, the chance of achieving sputum conversion is limited.

If the patient remains smear-positive after the completion of the continuation phase as outlined in Table above, he or she is no longer eligible for the retreatment regimen.

Relapse and treatment failure in patients in patients who are smear-negative may be managed according to the same principles. Those patients who failed to complete an adequate course of treatment, but who do not meet any of the above definitions of active disease when subsequently rediscovered should complete the retreatment regimen. The patient is best managed in a referral center.

Category III[@]

In this category childhood tuberculosis is one of the important groups as well as young people during adolescence with primary tuberculosis manifesting as pleural effusion or small parenchymal lesions. The treatment priority is higher as a proportion of these will become sputum-positive if not treated. The priority is lower in more benign forms of extrapulmonary tuberculosis. In pulmonary tuberculosis with parenchymal involvement exceeding a total of 10 cm^2 on chest skiagram, or in extrapulmonary tuberculosis with the incomplete remission of signs or symptoms, the continuation phase should be extended by administering isoniazid alone for an additional four months. Thiacetazone can be replaced for ethambutol where there is resource problem, but with precaution of HIV infection.

Category IV

The priority of treatment for this category is low. There is a high likelihood of multidrug-resistant tuberculosis. Even with optimal therapy, cure may be possible in only 50% of cases. Second line drugs are very expensive, toxic, and are less effective than conventional regimens in drug-susceptible cases. Prolonged hospitalization may be necessary.

If possible, the drug sensitivity of the bacilli should be established. A retreatment program may be attempted with second line and experimental drugs. In countries with limited resources, these cases are given low priority so that resources are not diverted from high priority cases. One may prescribe lifelong isoniazid for such patients where the renewed regimen as outlined is not feasible. The rationale of such single therapy with isoniazid is that the drug may diminish their infectivity and reduce the transmission of resistant organism.

SUPERVISION OF CHEMOTHERAPY

Poor compliance by the patient is by far the most important cause of poor results even from the most potent regimens under program conditions. The poor compliance is due to a number of factors, including the unpleasantness of taking tablets and capsules daily, forgetfulness (a common human nature), cost, inconvenience for the patient to collect drugs regularly, side effects of the drugs, etc. The importance of complying with the treatment throughout the whole duration of therapy must repeatedly be emphasized to the patient and to his family. Whenever possible every dose of the regimen should be administered under full supervision. In some countries this can be achieved by medical service staff on an entirely outpatient basis. In others, service staff can provide full outpatient supervision in the urban, but not in the rural areas, while in others treatment is rarely, if ever, fully supervised by service staff. Paramedical or laypersons, including a member of the patient's family, can be taught to do so.

It is well established that domiciliary therapy is preferable because of many socioeconomic reasons and is fully effective. It is not necessary to admit patients of tuberculosis for better supervision in hospitals except in certain special circumstances like a complication (hemoptysis, respiratory failure, cor pulmonale, etc.); for surgery, severe disease with hypotension, toxemia, complication due to drug therapy (hepatitis), surgery, and in cases of treatment failures for evaluation. It is better to accustom the patient to receive chemotherapy regularly and correctly on an outpatient basis from the

---

[@] Category III has been now merged with Cat I as latest Oct 2010 revision of RNTCP.

start, organizing supervision as efficiently as circumstances allow.

Whatever may be the level of supervision, compliance should be monitored by measures like periodic pill counting, and surprising urine tests for isoniazid or inspection of the urine for red coloration of rifampicin or can be detected in urine by chloroform extraction.

Under program conditions, Direct Observed Therapy (DOT) is now the practice world over. The subject is discussed in more details subsequently.

Antitubercular Drugs

SK Katiyar, S Katiyar

INTRODUCTION

Mycobacterium tuberculosis (MTB) is a slow growing organism that has the ability to enter a state of dormancy, which allows it to persist in the host despite adequate treatment. The low oxygen tensions prevailing in solid caseous tissue do not favor rapid multiplication of bacilli. Following liquefaction, caseation and cavity formation, the prevailing oxygen tension becomes higher, favoring extracellular bacillary multiplication. In a patient with Tuberculosis (TB), there are three kinds of populations of MTB organisms:[1] The first population is the actively growing extracellular organisms—huge numbers of organisms can grow extracellular in pulmonary cavities within liquefied caseous debris, it is this population, which develops drug-resistance most rapidly; the second population consists of slow growing or intermittently growing organisms (spurts of metabolism), which are inside macrophages; the third population is made up of slow growing organisms, which grow in solid caseous material. This environment is neutral in pH, but the penetration of drugs into this area may be compromised by a poor blood supply.

From studies of the fall in sputum bacterial counts in the early days of treatment with single drugs, it has been established that isoniazid is the most potent bactericidal agent, rifampicin is less bactericidal, while streptomycin and pyrazinamide have only low bactericidal activity.[2] Rifampicin is the only drug that is bactericidal against all three populations. Isoniazid and streptomycin are bactericidal against extracellular organisms (especially in cavity walls) and isoniazid also has bactericidal activity against intracellular bacilli. Pyrazinamide is bactericidal against intracellular organisms and works well in an acidic pH. Ethambutol is a bacteriostatic drug. Finally, a fourth population of totally dormant bacilli, not killed by any drug, is believed to exist. The sterilizing activity of drugs has been particularly studied in the experimentally infected mouse, where rifampicin and pyrazinamide were found to be very potent sterilizing drugs.[3] Among the alternative drugs, the quinolones have the highest bactericidal activity against MTB.[4]

It has been estimated that the population of slowly growing organisms in macrophages and caseous lesions/tissues is less than 10^5, whereas in cavities, the rapidly growing population numbers 10^7–10^9 organisms.[1] Since mutants resistant to streptomycin, isoniazid and ethambutol in wild strains of tubercle bacilli number 1 per 10^5–10^6 organisms and those resistant to rifampicin 1 per 10^7, such strains could easily be selected by therapy with one drug. Such selection is avoided by multiple drug therapy. Also, the other important factor leading to drug-resistance is adding a single drug to a failing regimen. In such case, the majority of the organisms, which are susceptible to that single drug will be killed, but the small number of organisms, which have spontaneously mutated will survive and multiply. Overtime, selection of drug-resistant organisms will occur. When formulating a therapeutic regimen for TB, it is important to remember that viable organisms from slow growing or intermittently growing population may persist if drugs are not continued for an adequate period of time.

It has now been established that the shortest course of chemotherapy required for adequate sterilization with currently available drugs is six months.[5] Modern drug treatment regimens consist of an initial or introductory phase of therapy followed by a maintenance or continuation phase of therapy. In order to prevent relapse and drug-resistance, clinicians must prescribe an adequate regimen and ensure that patients adhere to therapy. To ensure adherence, Directly Observed Therapy (DOT) should be considered for all cases. There are many factors that may influence patients' compliance, which include patients' social characteristics, personality, understanding of the illness and treatment, and patient-doctor relationship.[6]

The antitubercular drugs can be grouped into five categories depending upon their pharmacotherapeutic characteristics. Group 1 consists of first line oral agents– isoniazid (H); rifampicin (R); ethambutol (E); pyrazinamide (Z); rifabutin (Rfb). Group 2 consists of injectable agents (streptomycin (S), kanamycin (Km); amikacin (Am); capreomycin (Cm)). Group 3 includes: fluoroquinolones (levofloxacin (Lfx); ofloxacin (Ofx); moxifloxacin (Mfx)). Group 4 features oral bacteriostatic second-line agents (ethionamide (Eto); protionamide (Pto); cycloserine (Cs); terizidone (Trd); *p*-aminosalicylic acid (PAS)). Group 5 consits of agents with unclear efficacy (Clofazimine (Cfz); linezolid (Lzd); amoxicillin/clavulanate (Amx/Clv); thioacetazone (Thz); imipenem/cilastatin (Ipm/Cln); high-dose isoniazid (high-dose H) and clarithromycin (Clr)). These drugs are not recommended by WHO for routine use in MDR-TB patients.

First-line drugs are those used in initial and maintenance chemotherapy unless drug resistance is known. Rifabutin is not on the WHO List of Essential Medicines. It has been added here as it is used routinely in patients on protease inhibitors in several settings. High-dose H is defined as 16–20 mg/kg per day.

ISONIAZID

Domagk, the discoverer of the first sulphonamide, with Fox and others synthesized several thiosemicarbazone derivatives in which the benzene ring was replaced with a pyridine ring and found that such derivatives retained antituberculous effects.[7,8] These studies eventually led to the discovery that an intermediate product, isoniazid ($C_6H_7N_3O$) had the most potent antituberculous action. Isoniazid (H or INH), a hydrazide of isonicotinic acid was first synthesized from ethyl isonicotinate and hydrazine hydrate in 1912 by Meyer and Malley in Prague.[9] Its use was not considered until 1945 when the observation of the antituberculous effect of nicotinamide by Chlorine[10] stimulated others to test pyridine derivatives for their antimycobacterial effects. The first clinical trial of INH was initiated at Sea View Hospital, Staten Island, New York in 1951, reported in April 1952.[11] INH was the one of the most active compounds used to treat and prevent tuberculosis worldwide. Its low cost, good bioavailability, relatively low-toxicity, excellent intracellular penetration and narrow spectrum of action make it an almost ideal antimicrobial agent.

INH is readily absorbed after oral or parenteral administration, gets distributed into all body fluids and intracellular compartments.[12] After oral administration, peak plasma concentration is achieved in 1 to 2 hours. Heavy meals, including both carbohydrate and fatty foodstuffs result in delayed absorption, with maximal concentrations ranging from 9 to 50%.[13,14] Individuals with extensive gastric surgery or those with resected or dysfunctional terminal ileum may fail to have normal absorption. In CSF, the concentration reaches about 20% of that in plasma. INH is minimally bound to serum proteins. The dosage of INH for adults is 5 mg/kg if given daily (max 300 mg) and 15 mg/kg if given twice-thrice weekly (max 900 mg). Similarly, for children the dosage is 10–20 mg/kg, 20–40 mg/kg and 15 mg/kg if given daily (max 300 mg), twice-weekly and thrice weekly (max 900 mg) respectively. In fetus, the serum concentration reaches 50% of that in the mother. INH achieves a concentration of 16.6 mg/ml with 300 mg dose after 3 hours and 12 to 25% of the usual infant dose of 10–20 mg/day is available to the infant from milk.[15,16] This may be a problem for the infant who is given INH for either treatment or for chemoprophylaxis especially in higher dosage, since about 1/5th of the daily therapeutic dose of INH is also ingested form milk by the infant. Such infants may be predisposed to convulsions due to pyridoxine deficiency.[17]

Minimal Inhibitory Concentration (MIC) of INH for majority (80%) of susceptible *M. tuberculosis* strains is less than 1 mg/ml (0.025 to 0.05 mg/ml).[18] The peak serum concentration is 3–5 mg/ml, far in excess of MIC required. The MIC of other pathogenic mycobacterial species (*M. kansasii*, *M. avium*, *M. haemophilium*) is higher in the range of more than 1 to 10 mg/ml, and hence these may fail to respond to INH.

Most of INH (75 to 95%) is excreted in metabolized form in urine within 24 hours.[12] The major metabolites are acetylisoniazid formed by acetaylation of INH by hepatic acetyltransferase, and isonicotinic acid formed by hydrolysis. None of the other biotransformation products have biological activity. The half-life of INH ranges from 0.5 to 1.5 hours in rapid acetylators and 2 to 4.5 hours in slow acetylators. The acetylation rate is related to genetic differences in host acetyltransferase activity. There are three groups of acetylation status: Fast, intermediate and slow. The NATZ IZA allele codes for fast acetylation. Rapid acetylators are homozygous, intermediate acetylators are heterozygous and slow acetylators do not possess this allele.[19] Acetyltransferase is predominantly found in liver and small intestine. Liver disease can reduce acetylation rates. Neither age nor gender influences INH acetylation. Distribution of acetylation genotypes varies by race with approximately 50% of Whites, Blacks and South Indians being rapid acetylators whereas 80 to 90% of Chinese, Japanese and Eskimos have this trait.[20-22]

Earlier studies suggested that rapid acetylators who were more likely to have poor therapeutic response developed chronic tuberculosis.[23] However, careful monitoring of drug intake in such patients revealed that acetylation status does not influence treatment outcome.[24,25] This stands true for patients on daily, twice or thrice weekly regimens. By contrast, rapid acetylators have consistently less favorable outcomes in once-weekly regimens. Small amounts of INH are also excreted in saliva, sputum and feces. Isoniazid is removed by hemodialysis and peritoneal dialysis. The half-life of INH can be increased by drugs, such as Para-aminosalicylic Acid (PAS), procainamide, chlorpromazine and decreased by ethanol and other drugs that induce cytochrome P-450. Isoniazid may increase phenytoin, warfarin and carbamazepine serum levels.

The mechanism of action of INH consists of the inhibition of mycolic acid synthesis, depletion of Nicotinamide Adenine Dinucleotide (NAD), incorporation of INH derivatives into NAD to form NAD analogs (which lead to nonfunctional coenzymes) and catalase peroxidase.[26-30] Isoniazid is a prodrug, must be activated by a bacterial catalase-peroxidase enzyme called KatG.[31] KatG couples the isonicotinic acyl with NADH to form isonicotinic acyl-NADH complex. This complex binds tightly to ketoenoylreductase known as InhA, thereby blocking the natural enoyl-AcpM substrate and the action of fatty acid synthase. This process inhibits the synthesis of mycolic acid, required for the mycobacterial cell wall.

Kruger-Theimer[30] proposed that after uptake, INH is oxidized by the organism's catalase-peroxidase system to Isonicotinic Acid (INA) and other products incorporated to NAD analog. These NAD analogs are no longer functional as coenzymes, hence the tubercle bacilli become unable to oxidize hydrogen by the usual dehydrogenase-cytochrome oxidase system to form water. Also, a compensatory oxidation of hydrogen by flavin enzymes sets in, which leads to intracellular accumulation of hydrogen peroxide and inhibits bacterial multiplication.

Adverse Effects

The hepatotoxicity associated with INH was reported to result from the toxic effect of the intermediate products monoacetylhydrazine and diacetylhydrazine produced by liver cytochrome P-450 mixed function oxidase. After a standard 300 mg dose of oral INH, rapid acetylators excrete 23% of the drug as monoacetylhydrazine and slow acetylators excrete 5%.[29] Hence, the former phenotype was believed to be associated with increased hepatotoxicity. Larger studies have shown no significant differences in the incidence of hepatotoxicity by host acetylation rate status.[32,33]

The incidence of hepatotoxicity increases with advancing age.[34] It is 0% for persons younger than 20 years, 0.3% for persons 20–34 years of age, 1.2% for persons of age 35–49 years and 2.3% for persons 50 years or older.[35] Other factors that predispose INH associated liver damage include excessive alcohol consumption, Intravenous (IV) drug abuse and pre-existing liver disease. Asymptomatic elevation of serum transaminase levels occur in as many as 20% of cases.[36] The incidence of hepatitis was higher in those who were taking both INH and rifampicin than those who took either INH plus other drugs without RIF or RIF plus other drugs without INH.[37] RIF induces an INH degradation pathway whereby more of the INH is hydrolyzed to form increased amounts of hydrazine, a potentially toxic compound.[38] Although the rate of acetylation does not change in the presence of liver disease, clearance of drug is diminished in severe liver impairment, hence the dose of INH must be reduced to 150–200 mg daily and serum levels monitored.[39,40]

Since only a small proportion of INH is excreted renally, the dose needs to be reduced only in patients with severe renal insufficiency (creatinine clearance < 10 mg/dl). However, normal daily doses of INH (300 mg or 5–6 mg/kg) can be given to patients with severe renal impairment as the administration of these doses in such cases will be equivalent to 8–9 mg/kg, which is well tolerated.[41] It has been demonstrated that reducing INH doses to 200 mg/day results in significant reduced therapeutic potency.[42] Keeping this background information in mind, most clinicians do not alter normal doses of isoniazid in the patients of Chronic Renal Failure (CRF). In patients undergoing periodic hemodialysis, INH must be given in usual dose just following hemodialysis for rapid acetylators, a reduced dose may be appropriate for slow acetylators.[43]

Isoniazid has been shown to interfere with the biological functions of the pyridoxine compounds resulting in various toxicities like peripheral neuropathy and anemia.[44] The likelihood of toxicity is related to the nutritional status of the patient, is dosage related, rarely occurring with standard 300 mg daily dose. Conditions that predispose to neuropathy increase the risk of this manifestation in INH therapy. Hence pyridoxine supplementation must be given for chronically undernourished persons, chronic alcoholics, pregnant women, adolescent girls, diabetic patients, patients with uremia, seizure disorders, advanced age and cancer patients. Because of the potential for interference by high doses of pyridoxine with the antituberculous activity of INH, no more than 10 mg per day should be used.[44]

The peripheral neuropathy is characteristically a "stocking-glove" type that commences with numbness and tingling, usually worse in the feet. Untreated, it may progress to disabling paresthesias, pain and weakness. The therapeutic dose of pyridoxine is 100 mg daily in such patients. Other less frequent neurological adverse effects that have been reported with INH are toxic encephalopathy, optic neuritis, cerebellar ataxia and psychiatric disturbances.[45,46] The mechanism by which these side effects occur has not been elucidated. Hypersensitivity reactions to INH are occasionally encountered, manifesting by the way of fever, pruritis, cutaneous eruptions (morbilliform, maculopapular, eruptive rash). The other rare side effects of INH are lupus like reactions, arthralgias, hematological disorders (anemia, agranulocytosis).[47,48]

The ingestion of toxic amounts of isoniazid causes recurrent seizures, profound metabolic acidosis, coma and even death. In adults, toxicity can occur with the acute ingestion of as little as 1.5 g of isoniazid. Doses larger than 30 mg per kg often produce seizures. When ingested in amounts of 80–150 mg/kg or more, isoniazid can be rapidly fatal. The first signs and symptoms of isoniazid toxicity usually appear 30 minutes to 2 hours after ingestion and include nausea, vomiting, slurred speech, dizziness, tachycardia and urinary retention, followed by stupor, coma and recurrent grandmal seizures. The seizures produced by isoniazid toxicity are often refractory to anticonvulsant therapy. Given in gram-per-gram amounts of the isoniazid ingested, pyridoxine (vitamin B_6) usually eliminates seizure activity and helps to correct the patient's metabolic acidosis. Isoniazid toxicity should be suspected in any patient who presents with refractory seizures and metabolic acidosis.

Mechanisms of Resistance to INH

1. Mutation in KatG gene reduces catalase-peroxidase (KatG) ability to activate prodrug INH to a range of highly reactive bactericidal species. This mutation is responsible for 22 to 64% of INH resistant cases.
2. Inh A gene produces NADH-dependent enoyl-ACP reductase, which is necessary for the production of mycolic acid in tubercle bacilli. Mutation of this gene leads to the upregulation of INH A and hence increased the production of mycolic acid. This mutation occurs in 20 to 34% of INH resistance (low level resistance, MIC ≤ 1 mg/ml) and this can be overcome by increasing the dosage of INH.
3. kas A gene produces β-Ketoacyl ACP synthase and mutation of this gene reduces INH ability to interfere with mycolic acid synthesis (low level resistance). Occurs in 14% of INH-resistant cases.
4. ahpC gene produces alkyl hydroperoxide reductase and mutation of this gene reduces INH activation (in 10% cases).
5. Mutation of the gene ndh (NADH dehydrogenase) results in the increased competition of NADH with INH-NAD to bind with inhA site.

RIFAMPICIN

Rifampicin (RIF) is a semi-synthetic broad-spectrum bactericidal antibiotic derived from *Amycolaptosis mediterranei* (formerly classified as *Streptomyces mediterranei).*[49] Out of many biologically active compounds identified from the crude extract, rifamycin B was the most stable, least toxic, but with moderate level of therapeutic activity. Further refinement of rifamycin B led to the synthesis of rifampin (rifamycin B to rifamycin O to rifamycin SV to rifampicin).[50,51] Rifampicin was synthesized initially in Italy in 1957, but introduced in to clinical use only in 1966, employed initially for the retreatment of drug-resistant treatment failure cases.[52] Several large clinical trials have demonstrated that RIF containing regimens effectively reduce the duration of the chemotherapy to less than nine months.[53-57] Also, RIF has contributed to the success of intermittent therapy.[57,58] Both the shortened duration and increased interval of dosages have improved patient compliance, hence RIF became a standard element of therapy by late 1970s.[59] In addition to its antituberculosis activity, it has a wide range of activity against other bacteria, including *Staphylococcus*, *Streptococcus*, *Clostridium*, coliforms, *Pseudomonas*, *Proteus*, *Salmonella*, *Shigella*, *Bacteroides* and *Legionella*.

Rifampicin's target is β subunit of mycobacterial RNA polymerase, which read the DNA target sequence and catalyzing the polymerization of the complementary RNA chain with ribonucleic triphosphate monomers.[60]

Binding of RIF with β subunit of RNA polymerase either inhibits the nascent RNA chain form translocating into the polymer site allosterically or decreases the affinity of the active site for short chain RNA transcripts.[61,62] This results in short oligoribonucleotides that rapidly diffuse out of the active center.

Although RIF has lesser Early Bactericidal Activity (EBA) than INH, it has superior sterilizing activity.[2,63] This sterilization activity has been attributed to RIF's ability to affect semidormant bacilli, which are sporadically active for the short periods of time (population-C).[64] These brief periods of time are insufficient for other equally effective bactericidal agents to work, but sufficient for RIF to exert its effects.[64] Rifampicin is better absorbed in acidic environment, hence both food and antacids must be avoided in relation to the time of its administration. When taken on an empty stomach, peak plasma levels of 6–7 μg/ml are reached at 3 hours and the drug has a half-life of about 5 hours.[65] The MICs of susceptible strains range from 0.06 to 0.25 μg/ml.[66]

It is partly deacetylated in the liver, excreted almost entirely in the bile; but there is enterohepatic circulation, some drug does appear in urine.[67] During the first few weeks of therapy, RIF induces accelerated rates at which it is deacetylated in the liver.[68] Since, desacetyl-rifampicin is excreted in the bile more rapidly than plain RIF, the peak concentration and serum half-life reduces during initial few weeks. Thus, the peak levels initially may reach 20 μg/ml or higher, the usual range seen later is between 8 and 12 μg/ml. No adjustment in dosage is necessary in patients with renal failure. The dosage of RIF is 10 mg/kg body weight (max 600 mg/day). Dosages of RIF exceeding this limit result in more drug bye-passing the liver and increased serum levels. Divided daily doses of RIF result in lower serum concentration, hence it must be given in a single daily dose. Although about 75% of the drug is protein bound, it penetrates well into tissues and cells. Therapeutic concentrations are reached in Cerebrospinal Fluid (CSF) when the meninges are inflamed.

Rifampicin accelerates the hepatic cytochrome P450 pathway and reduces the serum levels of many drugs, including the antifungal agents, corticosteroids, warfarin and oral hypoglycemic agents (Table 43.1). Rifampicin also reduces the levels of protease inhibitors and non-nucleoside reverse transcriptase inhibitors used to treat Human Immunodeficiency Virus (HIV) infection.[69] This interaction may lead to the rapid development of resistance in HIV strains to the protease inhibitors. Rifampicin reduces the effectiveness of oral contraceptives[70] and patients should be advised to use nonhormonal contraception during, and for one month after, treatment with rifampicin-containing regimens.

TABLE 43.1: Drug interactions of rifamycins with other compounds[71-73]

A. Cytochrome P450 pathway induction, resulting in more rapid elimination of:

1. Corticosteroids
2. Oral contraceptives
3. Warfarin
4. Protease inhibitors
5. Azole antifungal agents
6. Anticonvulsants (phenytoin)
7. Oral hypoglycemic agents
8. Opiates (methadone)
9. Benzodiazepines
10. Antiarrhythmic agents
11. Chloramphenicol
12. Theophylline
13. Cyclosporine

B. Drugs that inhibit Cyp P450, hence retard elimination of rifamycins

1. Ciprofloxacin
2. Macrolides
3. Azol antifungals

Rifampicin is the most potent inducer of Cyp P450 enzyme, rifapentine is about 50% as active and rifabutin about 10%. Maximum induction of the Cytochrome P450 pathway may require 7 to 10 days; conversely these effects do not resolve for 7 to 14 days following the discontinuation of rifampin. If major drug-drug interactions are feared one may either substitute rifabutin or adjust upward the doses of the other drugs.

Rifampicin may be detected in urine following the extraction of 10 ml urine by analytical-grade chloroform in a screw-capped tube by gentle tilting.[74] The test is negative if no color develops, a yellow to orange color in the chloroform layer indicating the presence of rifampicin. The test is valid for up to at least 6 hours and, in some patients, up to 12 hours after the ingestion of rifampicin. Tetracyclines, nitrofurantoin and phenothiazine derivatives also give a yellow color.

Adverse Effects

Rifampicin is well-tolerated by most patients at the currently recommended dosages. Unlike other drugs, RIF produces some adverse reactions more frequently with intermittent than with daily regimens. Moreover, the risk of adverse effects increases with the interval between doses, thus toxicity is high, if treatment is taken only once a week.

The drug is excreted in body fluids, all patients should be warned that their urine, sweat and tears may be colored orange-pink. It may also discolorize soft contact lens. Of the Gastrointestinal (GI) reactions, nausea, anorexia and mild abdominal pain are most common, vomiting and diarrhea occurring less frequently. The incidence of these effects varies from 0 to 17%, more common in the elderly.[75,76] They may be resolved by giving the drug at night or, if this fails, during a meal. Transient elevations in aspartate aminotransferase levels are common (14 to 40% of patients), are of no clinical significance.[77] Major elevations of aspartate aminotransferase (>150 IU/l) occur in 4% and hepatitis with jaundice in about 1% patients. Rifampicin can also competitively interfere with the excretion of bilirubin and transiently elevate serum bilirubin.[78] Risk groups for jaundice include elderly women, alcoholics and those with a previous history of liver or biliary disease.[79] Rifampicin should be administered with care to these groups.

Cutaneous reactions are usually mild, consist of flushing with or without itching or a rash, commonly occur 2–3 hours after taking the drug. Patients usually desensitize themselves to these reactions, but occasionally an antihistamine may be required. Severe conjunctivitis and chronic papular acneiform reactions of the head, neck and shoulders have also been described. Cases of osteomalacia, pseudomembranous colitis, pseudoadrenal crisis, light-chain proteinuria with renal failure and cutaneous vasculitis have also been described.[80-82] Several other syndromes may occur with the intermittent regimens of rifampicin.

The "flu syndrome", with flu-like symptoms, lasting for up to 8 hours after administration of the drug, may occur a few months after treatment has been started, attributed to the development of circulating rifampicin-dependent antibodies.[83] It may resolve spontaneously or necessitate a switch to a daily regimen. Thrombocytopenic purpura constitutes an absolute indication for stopping therapy with rifampicin permanently. Asthmatic and hypotensive syndromes may occur separately or together, require corticosteroid therapy before conversion to a daily regimen. Acute hemolytic anemia and acute tubular necrosis have also been reported. Cutaneous syndromes usually start during the first month, and gastrointestinal symptoms are spread over the first-six months. The "flu" syndrome, observed only with intermittent regimens, generally begins in the third to fifth month of the treatment.[84] The incidence of side effects in recent reports of intermittent therapy have been gratifyingly low.[85,86] Anyone who develops serious allergic drug reactions, such as renal failure, thrombocytopenia or respiratory insufficiency should not receive rifampin again.

Mechanism of Resistance to RIF

Single base pair changes in the central region of the RNA polymerase beta subunit gene (rpo B) result in rifampin resistance. These mutations lead to decreased enzyme affinity for RIF.[87,88]

STREPTOMYCIN

Streptomycin (SM) was originally isolated from two strains of an actinomycetes species *(Streptomyces griseus)* by Selman Waksman and coworkers in 1943. Streptomycin was the first clinically effective drug available for the treatment of tuberculosis. Utility of this drug has been limited by the need for large doses that cannot be administered orally; frequent side effects and rapid emergence of resistance. Sole therapy with streptomycin in the late 1940s and early 1950s demonstrated the difficulty of treating TB with a single agent. As many as 80% of patients with cavitary disease harboring the large number of bacilli developed resistance to SM after the three months of therapy. It soon became evident that combination chemotherapy with newer agents prevented the emergence of drug resistance, hence SM was used along with PAS until isoniazid was developed.

Streptomycin does not cross most membranes due to its large size and cationic charge, hence oral absorption is very poor. It must be given by either intramuscular or intravenous route. It diffuses readily into most body tissues, but penetration into CSF is less, with maximum levels obtained in inflamed meninges, of about 25% of serum levels.[89] For this reason, SM is not usually recommended for TB meningitis. When no other agents are available, intrathecal or intraventricular administration is advisable in life-threatening cases.[90] The peak plasma levels in the range of 40 µg/ml are achieved 1 hour after injection and MICs are maintained for at least 8 hours.[91] Most strains of *M. tuberculosis* are inhibited *in vitro* at a concentration of 8 µg/ml. The drug is excreted almost entirely by glomerular filtration, dosage must be modified in renal failure to avoid toxicity. A safe rule is to multiply the daily dose by the ratio of the patient's creatinine clearance to normal creatinine clearance.

Streptomycin binds with 30S subunit of ribosomes, reduces protein synthesis and induces misreading of mRNA. Some experts do not feel this sufficiently explains the bactericidal action of SM as agents that affect protein synthesis are generally bacteriostatic, not lethal to cells.[92] The other proposed mechanisms of action include increased permeability of membranes and enhanced uptake of drug.

It crosses the placenta, fetal serum levels are about half those in maternal blood. Use of streptomycin showed increase in the incidence of malformations in infants, 16.9% versus 1.4 to 6.0% in controls.[93] Aminoglycosides should not be used in pregnancy. The level of the drug in breast milk ranges from 12 to 47% after 6 hours of a dose. Thus, the potential for side effects exist and SM should not be used if alternatives are available. Streptomycin sulfate for intramuscular injection is supplied as a powder in vials and should be reconstituted immediately before use. The dose of SM in adults is 15 mg/kg body weight daily or thrice weekly. The dose should be reduced to 0.5 gm/day for patients of age more than 50 years.

Adverse Effects

Streptomycin is toxic to the eighth cranial nerve, with vestibular damage more common than auditory damage. The patient usually complains of the progressive giddiness and unsteadiness of gait. Nystagmus may be present. The damage to the nerve is permanent, but most patients eventually compensate via ocular and proprioceptive compensatory mechanisms. The risk increases with the dose of drug and age.[94,95] The sensorineural deafness is most marked at higher frequencies. The first sign of ototoxicity is usually tinnitus or headache, which should prompt testing for hearing acuity with particular attention to deficits in the higher frequencies.

Streptomycin is ototoxic to the fetus. Other adverse effects include rashes, anaphylaxis, renal tubular damage, precipitation of heart failure, visual scotomas, peripheral neuritis, perioral paresthesia and blood dyscrasias, including hemolytic and aplastic anemia, agranulocytosis and thrombocytopenia. Streptomycin potentiates the neuromuscular block produced by curare, is contraindicated in individuals suffering from myasthenia gravis.

Mechanism of Drug Resistance

Mutation of rpsL gene (which encodes for S12 ribosomal protein) reduces the binding of streptomycin to S12 ribosomal protein and leads to the resistance.

PYRAZINAMIDE

Pyrazinamide (PZA), an amide derivative of pyrazine-2-carboxylic acid, was synthesized by Kushner and coworkers, and found to be the most active nicotinamide analog against *M. tuberculosis*.[96] The first clinical trial of PZA given as single agent, at an average dose of 2.8 gm/day demonstrated bacteriological and clinical improvement in most patients.[97] However, this effect was not sustained and resistance to PZA developed rapidly. In all earlier clinical trials, the dosage of PZA was very high (ranges from 40 to 70 mg/kg), which resulted in lethal hepatotoxicity.[98,99] Thus, PZA was used as second line agent until 1970. Trials of short-course chemotherapy for tuberculosis in the 1970s revived interest in PZA and suggested that PZA was essential to reduce the duration of therapy for smear positive pulmonary tuberculosis to six months. The relapse rates were very low (1.4 to 2.4% at 5 years) without increased toxicity. It was also noted in subsequent studies, that there was no additional utility of PZA if used beyond initial two months.[100] A modest, but significant reduction in serum RIF level was observed when PZA was given simultaneously.[101] Also, PZA caused a slight reduction in the bactericidal activity of RIF.[102] These studies clearly indicated that PZA need not be used beyond the first-two months, unless drug resistance was detected.

Currently, PZA is considered a first line agent, is the third most important drug used in the treatment of tuberculosis. The exact mechanism of the antimycobacterial action of PZA is not completely known. It is bactericidal in an acid environment ($pH<5.0$), hence its activity can be demonstrated *in vitro* only in low pH environment. Initially, it was thought that such acidic milieu was present in the phagolysosomes of macrophages. The tubercle bacilli produces an enzyme called “pyrazinamidase”, which converts PZA to Pyrazinoic Acid (POA),[103] reduces the pH and is inhibitory to tubercle bacilli. At the same time, the bacilli produces ammonia, neutralize pH, hence the effect of PZA on macrophage diminishes 4 to 7 days after infection.[104] Extreme regional acidity within the localized regions of the diseased host has been offered as another theory to explain PZA’s activity. It had been suggested that the local milieu in necrotic, caseating lesions is acidic that results in the inhibition or semidormancy of the tubercle bacilli, therefore PZA may contribute uniquely to chemotherapy by killing bacilli in this state, wherein they are not vulnerable to other agents, which only act on proliferating bacilli.[105,106] However, this activity of PZA was termed as "sterilizing" rather than a classic "bactericidal" effect. *M. bovis* is resistant to this drug.

It is well absorbed from the gastrointestinal tract, with the peak concentrations of about 50 µg/ml occurring 1.5 to 2 hours after ingestion. At a pH of 5.5, the minimal inhibitory concentration of pyrazinamide for *M. tuberculosis* is 20 µg/ml. It penetrates well into tissues, including the CSF. The drug is excreted in urine, 40% as pyrazinoic acid and 3% as unchanged PZA. The dose of pyrazinamide is 25–35 mg/kg body weight, daily. Lyophilized form of morphazinamide may be used for intravenous therapy if required, administered by drip infusion in a dose of 1G following reconstitution with solvent.

Adverse Effects

Hepatitis was commoner when the higher doses of the drug were used than are now recommended. It occurs in about 1% of patients, but milder subclinical derangement of liver function tests is common. The drug should be administered with caution to those with a history of liver or biliary tract disease. There is no significant increase in hepatotoxicity when pyrazinamide in standard dosage is added to a regimen of isoniazid and rifampicin during the initial two months of therapy.[107] Unlike RIF or INH-induced hepatitis, wherein values typically normalize in 10 to 14 days, PZA induced hepatitis may persist for 4 to 6 weeks after the drug has been discontinued.

Cutaneous reactions in the form of faintly erythematous rash and mild pruritus are rarely reported. Arthralgia is a common adverse effect (occurs in 40% of patients) that appears in the first-two months of treatment, more frequently in Chinese patients. It is due to the inhibition of renal tubular secretion of uric acid by pyrazinoic acid, the main metabolite of pyrazinamide, can be treated with nonsteroidal anti-inflammatory agents.[108] High serum concentration of uric acid may uncommonly precipitate gout. Rarer adverse effects include anorexia, nausea, vomiting and sideroblastic anemia.

Mechanism of Drug Resistance

Mutation of pncA gene (which encodes for pyrazinamidase) results in the blocking of conversion form PZA to pyrazinoic acid (active intermediate).

ETHAMBUTOL

Ethambutol (d-ethylenediimino-di-1-butanol) is a singular compound, not related to any other family of antimicrobial agents. The effectiveness of this drug in tuberculosis was first described in 1961.[109] Ethambutol (EMB) is generally considered as a bacteriostatic drug, although it is bactericidal *in vitro*.[110] It interferes with synthesis of arabinogalactan and with the transfer of mycolic acids into mycobacterial wall.[111] It has high Early Bactericidal Activity (EBA), reducing the number of bacilli in sputum over 14 days at a rate second only to INH.[2] Studies of EMB activity have indicated that high concentrations of EMB (10 µg/ml) have considerable bactericidal activity against *M. tuberculosis*.[112] Since, these high concentrations were achievable with dosages given in intermittent therapy, there appeared a role for EMB in twice-thrice weekly treatment. However, the available data indicate that EMB has only modest activity in drug susceptible tuberculosis, if given in the regimens containing INH, RIF and PZA. The major utility of EMB was demonstrated in the BMRC trials for cases with initial drug resistance to INH and/or SM.[113] In such cases, the primary effect of EMB is to prevent the treatment failure and further acquisition of drug resistance. However, SM appears slightly more potent than EMB as a fourth drug to accompany INH, RIF and PZA.

It is well absorbed after ingestion, with the peak plasma levels of 4 µg/ml occurring 2 to 4 hours after a dose of 15 mg/kg; food does not interfere with EMB absorption. The dose of EMB is 15–20 mg/kg body weight daily, 30 mg/kg thrice weekly and 40 mg/kg if given twice weekly. Peak levels correlate with the dosage. CSF concentrations of EMB are low (1–2 µg/ml with a dose of 25 mg/kg) even in the presence of meningitis. The drug is excreted in the urine, dosage adjustment is required for patients with renal insufficiency.[114] In patients on hemodialysis, a daily dose of 5 mg/kg body weight or a dose of 1.5 mg/kg every 8 hours has been suggested, with the testing of serum EMB levels and visual acuity, the serum levels should not exceed 5 µg/ml.[115] Levels of 1.5 mg/l and 4.6 mg/l have been observed in the milk of lactating mother. Hence an infant of 3.5 kg body weight would ingest 0.5–0.9 mg/kg/day from breast milk (2.8 to 6.9% of pediatric therapeutic dose), this is not likely to be toxic for the infant.[116]

Adverse Effects

The principal adverse effect of EMB is retrobulbar neuritis, presenting with blurred vision, central scotomas and disturbance of red–green vision.[117,118] Recovery is the rule if the drug is stopped at the first sign of visual problems, but if these are ignored, optic atrophy may result. This complication is uncommon at a dose of

15 mg/kg, but increases with a daily dose of 25 mg/kg. Pre-existing ophthalmic diseases may predispose to EMB toxicity. Patients should be warned to report visual symptoms immediately and to stop treatment if symptoms develop; pretreatment testing and recording of visual acuity is advised for patients taking this drug. The renal clearance of urates is decreased by EMB in a significant number of normal patients, and acute attacks of gout have been precipitated in patients at risk.[119] Other adverse reactions of EMB occasionally described are: Anaphylaxis, skin rashes, hepatic dysfunction, blood dyscrasias, interstitial nephritis and peripheral neuropathies.

Mechanism of Drug Resistance

Mutation of embB gene (which encodes for a membrane protein) reduces the binding of ethambutol with the membrane protein and leads to resistance to EMB. This mutation is responsible for 48 to 62% of cases resistant to EMB.

QUINOLONES

The quinolones are derivatives of pyridinecarboxylic acid, initially derived from an intermediate in chloroquine synthesis.[120] The 6-fluoroquinolones are potent antibacterial agents that interfere with a wide variety of DNA related processes, primarily through their action on A subunit of DNA gyrase (topoisomerase), the enzyme responsible for introducing supercoils into bacterial DNA. The fluoroquinolones have both bactericidal and sterilizing activities. These are well absorbed in gastrointestinal tract and the bioavailability approaches 100%. It is distributed widely in the body, 30 to 50% of serum concentration is attained in CSF with inflamed meninges. It has minimal hepatic metabolism; 87% of dose is excreted unchanged in the urine within 48 hours via glomerular filtration and tubular secretion. Dose reduction is necessary in patients with renal failure. Animal data demonstrated arthro-pathy in immature animals, with erosions in joint cartilage. Quinolones should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Ciprofloxacin is no longer recommended to treat drug-susceptible or drug resistant tuberculosis.[121] Currently, the most potent available fluoroquinolones in descending order based on *in vitro* activity and animal studies are: Moxifloxacin = gatifloxacin > levofloxacin > ofloxacin.[122,123] While ofloxacin is commonly used because of relatively lower cost, the later-generation fluoroquinolones, moxifloxacin and levofloxacin, are more effective and have similar adverse effect profiles. Furthermore, the later-generation fluoroquinolones may have some efficacy against ofloxacin-resistant strains.[124] Although similar to moxifloxacin in its efficacy against TB, gatifloxacin is associated with serious cases of hypoglycemia, hyperglycemia and new-onset diabetes. If gatifloxacin is used, it should undergo close monitoring; the drug has been removed from the markets of many countries. Levofloxacin is, for the time being, the fluoroquinolone of choice until more data confirm the long-term safety of moxifloxacin. A later-generation fluoroquinolone is recommended for the treatment of XDR-TB, although there is inadequate evidence on whether this is an effective strategy.

Adverse Effects

The quinolones are generally well-tolerated. Gastrointestinal intolerance, headache, malaise, insomnia, restlessness, dizziness, allergic reactions, diarrhea, photosensitivity, tendon rupture and peripheral neuropathy have rarely been reported. Quinolones have the potential to cause tachycardia and QTc prolongation, can cause serious arrhythmia. This potential has been most marked for gatifloxacin and sparfloxacin, less seen in other quinolones. These drugs should be avoided in the presence of hypokalemia and in those patients taking drugs that can prolong QT such as cisapride, tricyclic antidepressants, phenothiazines, class IA and class III antiarrhythmics and macrolides.

Mechanism of Drug Resistance

Mutation of gyrA gene (which encodes for bacterial DNA gyrase A subunit) results in the inability of fluoroquinolones to inhibit DNA gyrase.

PARA-AMINOSALICYLIC ACID (PAS)

Lehman studied 50 related compounds of salicylates and found PAS the most active against tubercle bacilli.[125] In a BMRC trial,[126] it was observed that there was no significant difference in the efficacy of streptomycin plus PAS versus streptomycin alone; however, a marked decrease in the development of streptomycin-resistant strains was noticed with addition of PAS. It was considered a first-line agent in combination with INH and SM until 1963 when ethambutol was approved for clinical use and replaced PAS as the first-line agent.

Para-aminosalicylic acid is a structural analog of Para-aminobenzoic Acid (PABA). It exerts a bacteriostatic effect on *M. tuberculosis* by competitively blocking the conversion of PABA into folic acid (which is essential for DNA synthesis), hence inhibits bacterial growth.[127] The MIC of sensitive strains ranges from 0.5 to 2.0 mg/ml.[131] The drug is readily absorbed from the gastrointestinal tract. The peak serum level of 7–8 mg/ml is reached within 1 to 2 hours after an oral dose of 4 gm. About 60 to 70% of the drug is bound to plasma proteins. PAS is metabolized in the liver by acetylation and excreted in urine as metabolites.[128] It does not cross non-inflamed meninges, rapidly diffuses into caseous lesions within 30 minutes, but rapidly disappears from the lesion as soon as drug administration is dis-continued.[129] The drug is excreted rapidly, thus larger doses must be given. The dose of PAS is 150 mg/kg daily in divided doses or 10–12 gm/day.

Adverse Reactions

Nearly all patients suffer gastrointestinal upset in the form of nausea, vomiting, anorexia or diarrhea. Many patients stop taking PAS prematurely. Hypersensitivity reactions manifested by fever, rashes, pruritus and hepatic dysfunction occur in about 5 to 10% of patients. In some patients, lymphadenopathy, joint pains and pulmonary infiltrates with eosinophilia have been reported. Most of these symptoms disappear with the discontinuation of therapy. It can cause fluid retention from excessive sodium load in patients with congestive cardiac failure. Hemolytic anemia has been reported in patients with G6PD deficiency. PAS partially inhibits the uptake of iodine by thyroid, thus can cause hypothyroidism.[130]

Mechanism of drug resistance to PAS is not known.

ETHIONAMIDE/PROTHIONAMIDE

Ethionamide (Alpha-ethyl-thioisonicotinamide) is a thioamide of isonicotinic acid that was synthesized by Lieberman in 1952.[131] The exact mechanism of action is unknown, but it appears to be similar to that of INH. Ethionamide is believed to exert its action on the outer envelope of tubercle bacilli, which includes the inhibition of mycolic acid synthesis.[131] The MIC of susceptible strains of *M. tuberculosis* is 0.3 µg/ml. The drug is well-absorbed from the GIT, the peak serum level is about 1.4 µg/ml after 3 hours of administration. After absorption, the drug gets widely distributed in the body, inactivated by liver and to a lesser extent by the kidney.[132] It is excreted in the kidney mainly as metabolites, about 5% as active drug. The drug readily crosses both the inflamed and the non-inflamed meninges, the concentration in CSF equals to the serum concentration.

Prothionamide is the N-propyl derivative of ethionamide, similar to ethionamide in its action, clinical effectiveness and toxicity. However, prothionamide is considered to be unpleasant of the two.

The maximum optimum daily dose of ethionamide and prothionamide is 15–20 mg/kg (max. 1 g/day), usually 500–750 mg. The dose must be reduced to 250–500 mg/day in patients with creatinine clearance of less than 30 ml/minute. Resistance develops rapidly if used alone, there is complete cross-resistance between ethionamide and prothionamide (partial cross-resistance with isoniazid and thiacetazone). Thiacetazone-resistant organisms are often sensitive to prothionamide, but the reverse does not apply.

Adverse Reactions

The most common side effect of ethionamide/prothionamide is gastrointestinal upset, which includes nausea, vomiting, unpleasant metallic taste and epigastric burning pain. Gastrointestinal effects may be minimized by decreasing dosage, by changing the time of drug administration, or by the concurrent administration of an antiemetic agent. Most of the symptoms disappear in a week, but in some the symptoms are severe requiring the discontinuation of therapy. Hepatitis with jaundice has been reported to occur in 4.3% of patients. Other side effects include mental depression, psychological disturbances, peripheral neuritis, convulsion, hypoglycemia, photosensitivity, gynecomastia, hypothyroidism, alopecia and acne. The drug is teratogenic in animals, should be avoided in pregnancy (at least during the first trimester) and care should be taken in the presence of diabetes, liver disease, alcoholism or mental illness. Ethionamide is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in animals and *in vitro* systems.

Mechanism of Drug Resistance

Mutation of inhA gene (similar to that in isoniazid) lead to resistance to ethionamide in 40% of resistant cases.

CYCLOSERINE/TERIZIDONE

Cycloserine introduced in 1955, is an antibiotic isolated by Harned and Kropp from the culture of *Streptomyces orchidaceous*. Cycloserine is a structural analog of D-alanine. It competitively blocks the enzymes alanine racemase and D-alanyl-D-alanine synthetase, which are necessary for the synthesis of D-alanine dipeptide. This dipeptide is essential for mycobacterial cell wall synthesis, inhibition of which leads to the inhibition of cell growth.[127] Cycloserine is bacteriostatic, the MIC is 10 µg/ml for susceptible strains. The drug is rapidly absorbed orally, a mean peak serum level of 50 µg/ml is achieved in 4 hours of drug intake. The drug is widely distributed in the body, crosses the meninges promptly regardless of inflammation. There is no cross-resistance with other antituberculosis drugs, 60 to 70% of the drug is excreted unchanged in the urine via glomerular filtration; small amount are excreted in feces and a small amount is metabolized.

Terizidone contains two molecules of cycloserine. It is used in some countries instead of cycloserine, assumed to be as efficacious; however, there are no direct studies comparing the two drugs. Terizidone is not yet recommended by the WHO. The dosage of cycloserine is 10–15 mg/kg daily (max. 1000 mg), usually 500–750 mg per day given in two divided doses.

Adverse Reactions

The frequently encountered adverse effects of cycloserine are neurological and psychiatric problems, including headaches, irritability, sleep disturbances, aggression, tremors, gum inflammation, pale skin, depression, confusion, dizziness, restlessness, anxiety, nightmares, severe headache and drowsiness. Occasionally, visual changes, skin rash, numbness, tingling or burning in hands and feet, jaundice, eye pain, rarely seizures, and suicidal thoughts may also occur. Neurotoxicity is dose related, monitoring of the blood level is recommended to avoid levels in excess of 30 µg/ml.

CAPREOMYCIN

Capreomycin has a different chemical structure from the aminoglycosides, but the mechanism of antibacterial activity is similar. Polypeptides appear to inhibit the translocation of the peptidyl-tRNA and the initiation of protein synthesis. Capreomycin is bactericidal in action. It has got no cross-resistance with aminoglycosides. It penetrates meninges, only if inflamed. Excretion of 50 to 60% of the drug is through kidneys and a small amount through biliary excretion. There is no significant oral absorption. Intramuscular absorption may be delayed if the same site is used consistently. Capreomycin is given in a daily dose of 15–20 mg/kg with a usual dose of 1 g in a single daily dose. When necessary, it is possible to give the drug at the same dose 2 or 3 times weekly during the continuation phase, under close monitoring for adverse effects. Levels should be monitored for patients with impaired renal function. Interval adjustment (12–15 mg/kg 2 or 3 times per week) is recommended for patients with creatinine clearance of less than 30 ml/min or on hemodialysis.

Adverse Reactions

Animal studies show teratogenic effect, hence it is contraindicated in pregnancy. The frequent side effects are nephrotoxicity (20 to 25%), tubular dysfunction, azotemia, proteinuria, urticaria or maculopapular rash. The other side effects that have been reported include ototoxicity (vestibular>auditory), electrolyte abnormalities (decreased blood levels of calcium, magnesium and potassium), pain, induration and sterile abscesses at injection sites.

THIACETAZONE

Thiacetazone is a low-potency, cheap drug given orally and frequently used as a companion drug for isoniazid in developing countries. It is bacteriostatic in its action. The mechanism of action is unknown. It is well absorbed in the gastrointestinal tract and excreted in urine. It crosses placental barrier and excreted in milk in a concentration equal to that in the mother's blood. It is given in an oral dose of 150 mg daily.

Adverse Reactions

The most frequent side effect is the GI upset, which includes nausea, abdominal discomfort, vomiting and diarrhea. Other adverse effects include anemia, agranulocytosis, thrombocytopenia, cerebral edema, conjunctivitis, blurred vision and jaundice. Thiacetazone may enhance the ototoxicity of streptomycin. Generalized reactions are common. Cutaneous hypersensitivity reactions progressing to toxic epidermal necrolysis have been reported in a significant percentage of patients with HIV-associated tuberculosis treated with thiacetazone-containing regimens. HIV-positive patients or those with clinical markers for Acquired Immunodeficiency Syndrome (AIDS) should have ethambutol substituted for thiacetazone in their treatment regimen.

GROUP 5 DRUGS

Group 5 drugs are not recommended for routine use in the treatment of drug-resistant tuberculosis because their contribution to the efficacy of multidrug regimens is unclear. Although they have demonstrated some activity *in vitro* or in animal models, there is little or no evidence of their efficacy in humans for the treatment of drug-resistant tuberculosis. Most of these drugs are expensive, in some cases require intravenous administration. However, they can be used in cases where adequate regimens are not possible to design with the medicines from Groups 1–4. They should be used in consultation with an expert in the treatment of drug resistance. If a situation requires the use of Group 5 drugs, it is recommended to use at least two drugs from the group, given the limited knowledge of their efficacy.

CLOFAZIMINE

Clofazimine (Cfz) is orally active (40 to 70% absorbed) and accumulates in many tissues, especially in fat. Usual adult dose is 100 to 300 mg daily. Some clinicians begin at 300 mg daily and decrease to 100 mg after 4 to 6 weeks.

The major side effect is reddish-black discoloration of skin, especially on exposed parts. Discoloration of hair, conjunctiva and body secretions can also occur. Dryness of skin and itching is often troublesome. Acneiform eruptions and phototoxicity have been reported. Enteritis with intermittent loose stools, nausea, abdominal pain, anorexia and weight loss can occur at higher dosage. The early syndrome is a reflection of irritant effect of the drug, subsides with dose adjustment and administration along with meals. A late syndrome occurring after the few months of therapy is due to the deposition of clofazimine crystals in the intestinal mucosa. Clofazimine is to be avoided in early pregnancy and in patients with severe liver or renal impairment.

LINEZOLID

Linezolid (Lzd) is a new class antimicrobial agent termed "Oxazolidinones", active against resistant gram-positive aerobes and anaerobes. It inhibits bacterial protein synthesis by binding to the 23S fraction of 50S ribosome and interferes with the formation of tRNA, stops protein synthesis at an early step. As such, there is no cross resistance with any other class of antimicrobial agents. It is rapidly and completely absorbed orally, partly metabolized nonenzymatically and excreted in urine. Usual adult dose is 600 mg twice daily, reduced to 600 mg once a day after 4 to 6 weeks to decrease adverse effects.

Side effects are mostly limited to abdominal pain and bowel upset. Occasionally, rashes, pruritus, headache and oral/vaginal candidiasis have been reported. It can cause thrombocytopenia and bone marrow depression.

AMOXICILLIN/CLAVULANATE

Amoxicillin/Clavulanate (Amx/Clv) is generally well tolerated, but GI tolerance is poorer especially in children. Dosages for the drug-resistant cases of tuberculosis are not well-defined. Normal adult dose is 675/125 mg twice a day or 500/125 mg three times a day. Dosages of 1000/250 have been used, but adverse side effects may limit this dosing. Candida stomatitis/vaginitis, rashes and hepatic injury have been reported.

IMIPENEM/CILASTATIN

Imipenem/cilastatin (Im/Cn) belongs to the subgroup of carbapenem. Imipenem has a broad-spectrum of activity against both sensitive and resistant aerobic and anaerobic gram-positive, as well as gram-negative bacteria. It acts by inhibiting cell wall synthesis. It remains very stable in the presence of beta-lactamase. Usual adult dose is 500–1000 mg IV every 6 hours. Common adverse drug reactions are nausea and vomiting. Those who are allergic to penicillin and other beta-lactam antibiotics should not take imipenem. It can also cause seizures.

CLARITHROMYCIN

Clarithromycin (Clr) belongs to the group "Macrolide" having a macrocyclic lactone ring with attached sugars. It is rapidly absorbed and has greater tissue distribution. No dose modification is needed in liver disease and in mild-to-moderate renal failure. It inhibits hepatic oxidation of many drugs and leads to rise in the plasma levels of theophylline, carbamazepine, valproate, warfarin, terfenadine, astemizole and cisapride. Usual adult dose of clarithromycin is 500 mg twice daily.

Side effects can occur in the form of GI upset, but it is better tolerated than erythromycin. A few cases of pseudomembranous enterocolitis, hepatic dysfunction or rhabdomyolysis have been reported. Several cases of Q-T prolongation and serious ventricular arrhythmia are reported due to the inhibition of CYP3A4 resulting in the high blood levels of concurrently administered terfenadine/astemizole/cisapride.

HIGH-DOSE ISONIAZID

Many experts feel that high-dose isoniazid (16–20 mg/kg daily) can still be used in the presence of resistance to low concentrations of isoniazid (>1% of bacilli resistant to 0.2 µg/ml, but susceptible to 1 µg/ml of isoniazid), whereas isoniazid is not recommended for high-dose resistance (>1% of bacilli resistant to 1 µg/ml of isoniazid).[133] One study from a low-resource setting where a standardized regimen was used, suggested that routine inclusion of high-dose isoniazid (16–20 mg/kg/day) could improve outcomes.[134]

Historical and Non-pharmacological Management of Pulmonary Tuberculosis

KB Gupta

INTRODUCTION

Since ancient time, tuberculosis (TB) has taken a heavy toll of lives. The disease is known for centuries and there have been continuous attempts to find a cure that involves many types of measures such as physical, chemical and others. The therapy for TB is directed to achieve five major purposes:

i. To kill the bacilli by adopting specific chemotherapy
ii. To eliminate the diseased tissue by resectional surgery
iii. To assist the healing of lesions by collapse measures
iv. To improve general resistance of the body
v. To improve quality of life by rehabilitation program.

HISTORY

Tuberculosis is known by different terms, including consumption, phthisis, scrofula, Pott's disease, white plague, Koch's disease, yaksma, consumption, "chaky oncay", each of which make reference to the "drying" or "wasting" effect of the illness.[1-3]

Signs of the disease have also been found in the Egyptian mummies dated between 3000 and 2400 BC.[4] The first reference to tuberculosis in Asian civilization is perhaps found in the Hindu "Vedas", the oldest of them (Rig-Veda, 2000 BC) calls the disease "yaksma." The "Atharvaveda" calls it by another name: "Balasa". It is in the Atharvaveda that the first description of scrofula is given. The "Sushruta Samhita", written around 600 BC, recommends that the disease be treated with breast milk, various meats, alcohol and rest. The "Yajurveda" advises sufferers to move to higher altitudes. The "Manusmriti", written around 1500 BC states that sufferers of yaksma are impure and prohibits "brahmans" from marrying any women that has a family history of the disease.

The first mention of tuberculosis in Chinese literature appears in a medical text written by emperor Shennong of China (2700 BC).·Yellow emperor, wrote "Huangdi Neijing", in which he describes "xulao bing" (weak consumptive disease), which is believed to be tuberculosis. Hippocrates (460–377 BC) described the characteristics, while Aristotle and Celsus also mentioned about the disease. Galen proposed a series of therapeutic treatments, including opium as a sleeping agent and painkiller, blood letting and a diet of barley water, fish and fruit.[3] In the famous library of Leipzig there is a folio, which contains information that Jesus had suffered from this illness.

During the dark ages (400-1400 BC), all the knowledge of the disease was lost. With the spread of Christianity, monarchs were seen as religious figures with magical or curative powers. It was believed that "royal touch", the touch of the sovereign of England or France, could cure diseases due to the divine right of sovereigns,[5] King Henry IV of France usually performed the rite once a week. Scrofula became known as the "King's evil". Touching the king's feet for the cure of king's evil (as tuberculous was then known) was prevalent during the 11th and 12th centuries in England and elsewhere. The infectious nature of the disease was described by Girolamo Fracastoro of Verona (1483-1553). Franciscus Sylvius of Leyden (1614-1672) first employed the term "tubercle" and stated that tubercles were seen in patients of consumptives.[5]

Seventeenth and Eighteenth Century

Franciscus Sylvius began differentiating between various forms of tuberculosis. He recognized that the skin ulcers caused by scrofula resembled tubercles seen in phthisis, thus, noted that "phthisis is the scrofula of the lung".[4] Thomas Willis concluded that all diseases of the chest must ultimately lead to consumption. Willis did not know the exact cause of the disease, but he blamed it on sugar or an acidity of the blood.[4] Benjamin Marten proposed in a new theory of consumption of the lungs that the cause of tuberculosis was some type of animacula: Microscopic living beings that were able to survive in a new body. Robert Whytt gave the first clinical description of tuberculosis meningitis.[6]

Nineteenth Century

The disease began to represent spiritual purity and temporal wealth, leading many young, upper-class women to purposefully pale their skin to achieve the consumptive appearance. Jean-Antoine Villemin demonstrated that the disease was indeed contagious, after conducting an experiment in which tuberculous matter from human cadavers was injected into laboratory rabbits, who then became infected.[3]

Robert Koch revealed for the first time on March 24, 1882, the causal agent of the disease: *Mycobacterium tuberculosis* or Koch's bacillus.[2,3,7] Rudolf Virchow (1821-1902), the founder of cellular pathology described the development of caseation in tuberculous tissue and believed that susceptibility to the disease was inherited and not the disease itself. In 1890, Koch developed tuberculin, a purified protein derivative of the bacteria.[8,9] It proved to be an ineffective means of immunization, but in 1908, Charles Mantoux found it was an effective intradermal test for diagnosing tuberculosis.[10]

Vaccine: The first genuine immunization against tuberculosis was developed from attenuated bovine-strain tuberculosis by Albert Calmette and Camille Guérin in 1906. It was called Bacille Calmette-Guérin (BCG).[11] The BCG vaccine was first used on humans in 1921 in France, but it was not until after the World War II that BCG received widespread acceptance in the United States, Great Britain and Germany.

Treatment: As the century progressed, some surgical interventions, including the pneumothorax or plombage technique—collapsing an infected lung to "rest" and allow the lesions to heal—were used to treat tuberculosis. Giorgio Baglivi reported a general improvement in tuberculosis sufferers after they received sword wounds to the chest. F Ramage induced the first successful therapeutic pneumothorax.[6]

In 1944, Albert Schatz, Elizabeth Bugie and Selman Waksman isolated *Streptomyces griseus* or streptomycin, the first antibiotic and the first bacterial agent effective against *M. tuberculosis*. This discovery is generally considered the beginning of the modern era of tuberculosis, although the true revolution began some years later in 1952, with the development of isoniazid, the first oral mycobactericidal drug. The advent of rifampin in the 1970s hastened recovery times and significantly reduced the number of tuberculosis cases until the 1980s.[6]

ANCIENT DRUGS IN THE TREATMENT OF TUBERCULOSIS

Before the discovery of conventional antituberculosis drugs, treatment of tuberculosis was mainly passive in nature. Many drugs, chemical or herbal, had been tried and used for the treatment of tuberculosis. Some of them are still in use while others have been abandoned due to their unacceptable benefit to risk ratios.

Drugs Used in the Past

Since ages, drugs like gold, arsenic, calcium, sulfur, plant extracts and animal products have been used in the hope of curing tuberculosis.

Gold compounds: Treatment of pulmonary tuberculosis with these compounds was introduced first by Robert Koch and later popularized by Danish physicians, in the mid-1920s, despite consistently negative experimental results, based on Paul Ehrlich's theories of antimicrobial drug effects. Although found as an effective antituberculosis drug, its toxicity resulted in its discard.[12]

Arsenic: Initially introduced by Koch, Burrow found that potassium arsenite prevented the growth of tubercle bacilli *in vitro*. The result of Burrow were contradicted by Nürnberger who observed no specific action in tuberculosis, or on the tubercle bacilli, *in vitro*.[13]

Calcium: Peterson and Levinson have reported more deaths among tuberculous patients with low blood calcium. Those patients with a higher blood calcium evidenced a healed or healing lesion and therefore, a good prognosis.[14]

Cod liver oil: Introduced as a treatment for pulmonary tuberculosis between the 1770s and the 1930s, cod liver oil was introduced into the British Pharmacopeia in 1771. By the end of the 18th century, it was a prominent treatment in the Manchester Infirmary. Cod liver oil entered medical practice in the United States in the 1840s, quickly gaining widespread use. After the discovery of the tubercle bacillus, some claimed that cod liver oil had specific action against the bacillus.[15]

Copper: Initially started by the Swiss physician Koechlin, based on a Chinese original, it was widely used in Central Europe to treat a range of skin, neurological and infectious diseases, including tuberculosis. Copper treatment for tuberculosis continued until the 1940s and various physicians reported on their success in using copper preparations in intravenous injections.[16]

Antimony: Percy Moxey used intramuscular injections of colloidal antimony for the treatment of tuberculosis.[17]

Mercury: It acts as tonic and renders the blood bactericidal, producing an antitoxin, which has direct effect on the bacilli.[18]

Herbal Drugs

In the great Vedas, there has been mention of certain herbs having medicinal properties against *M. tuberculosis*. Herbal drugs are used in Ayurvedic medicine, may have some role in the treatment of tuberculosis. Several herbal drugs as below, have been used in the past, but none has been shown to have a proven clinical value.

i. *Ashwagandha:* Its extract contains at least 13 heterogeneous alkaloids, which are chemically identified as, pyridine, pepindinine, sonine and free amino acids.[19] These alkaloids show:
    - Anti-inflammatory and antipyretic effects
    - Inhibit growth of gram-positive aerobic and mycobacterial organisms
    - Suppress granuloma formation
    - Antitumor activity and immunomodulation
    - Increase in T lymphocytes level in TB patients.

ii. *Licorice (Glycyrrhiza glabra L.; Family: Papilionaceae/ Fabaceae):* The activity guided fractionation of ethanolic extract from the roots of Glycyrrhiza glabra and subsequent phytochemical analysis resulted in identifying glabridin as the active constituent and hispaglabridin B as inactive constituent against *M. tuberculosis*. The antimycobacterial activity of root ethanolic extract was observed at 500 gm/ml against *M. tuberculosis* H37Ra and H37Rv strains through BACTEC assay. The MIC of test compounds was noted on the basis of GI (growth index) value. Further, the ethyl acetate fraction showed better activity at a concentration range of 100 to 250 g/ml.[20]

iii. *Allium sativum:* The inhibitory effect of garlic on *M. tuberculosis* has been mentioned in clinical reports for nearly 100 years. Delaha and Vincent studied the inhibitory effect of garlic extract on mycobacteria.[21] In an another study in patients of tubercular lymphadenitis, garlic extracts or compounds have shown a good potential as antitubercular(s) drug, if given as a supplement to ATT.[22]

iv. *Asparagus racemosus:* Roots of asparagus racemosus Willd (Shatavari) are widely used in Ayurveda as “Rasayana” for immunostimulation.[23]

Other Plant Extracts

In South Africa, antimicrobial properties of certain plant extracts, which were used by traditional healers for the treatment of tuberculosis like Artemisia afra Jacq. ex Willd, Carpobrotus edulis L, Tulbaghia violacea Harv. were studied for activity against *B. cereus, E. coli*, *Klebseilla pneumoniae*, *S. aureus* and *Mycobacterium aurum* A+ strain using two fold microdilution bioassay.[24]

Astragalus membranaceus is a herb used in traditional Chinese medicine to boost immunity.[25]

Plant extracts obtained from Euphorbia cerebrosides and Cetraria usnic acid have inhibitory activities comparable to standard antituberculosis drugs. Rhododendron, Melaleuca and Leptospermum essential oils had minimal inhibitory concentration in a range of 0.25 to 0.025%. Most plant extracts had no toxic effect against human cells *in vitro*.[26]

Certain plant extracts like Emblica officinalis and Tinospora cordifolia showed hepatoprotective properties against antituberculosis drug-induced liver injury.[27]

Homeopathic medicines used for the treatment of scrofula tuberculosis.[28] For example, Calcarea carbonica, sulfur, Baryta carbonica, silicea, graphite and mercurius.

Drugs used in Unani system[29] for the symptomatic treatment of:

i. *Fever:* Tukhm anisoon (pimpinella anisum) seeds, rRb-u-soos, Persiawashan, barley husk cooked with crab, massage of sandal, camphor and rose water on chest.

ii. *Cough:* White opium seeds, gum, starch, Kateera, Bambusa arundinacea

iii. *Hemoptysis:* Curd milk from which cream is removed and hot iron pieces are added to it and cooked.

SANATORIUM TREATMENT

Sanatorium is an institute in good climate. The sanatoria started in 18th century and continued in the 19th century

TABLE 44.1: Evolution of sanatoria for treatment of tuberculosis

A-Global	
Year	*Name of sanatorium*
19th Century	
1863	Brehmerschen Heilanstlt für Lungenkranke in Gabersdorf (Sokolowsko), Silesia.
1882	Adirondack Cottage Sanatorium in Saranac Lake, New York
20th Century	
1911	Burkevillae, Virginia's Piedmont Sanatorium, USA Waverly Hills Sanatorium, USA
1930	Paimio Sanatorium, Finland Helianitia Sanatorium in Valadares, Purtgal
B-India	
Year	*Name of Sanatorium*
1906	Missionary TB Sanatorium, Tilonia, Ajmer
1908	Missionary TB Sanatorium, Almora
1909	TB Sanatorium, Dharampur, Shimla
1912	United Mission Tuberculosis Sanatorium, Madanapalle
1917	TB Dispensary, Bombay and Madras[30,31]

till the development of the concept that domiciliary treatment is as effective as sanatorium treatment (Table 44.1). The essential features of sanatorium treatment are the following:

i. Close and skilled supervision in good surroundings.
ii. Proper training of the individual in hygienic living, particularly in respect to breathing fresh air, taking adequate rest, feeding rationally and preventing infection.[32,33]

Role of Sunlight

Throughout history, the sun has been respected for its healing power. In ancient Greece, physicians employed symptom-specific techniques of solar therapy by placing patients in specially constructed healing temples in the suncity of Heliopolis. Early in the 20th century, prior to discovery of antibiotics, European physicians sent their tuberculosis patients to hospital in Swiss and Austrian Alps. Sunlight promotes good immune function and helps to fight infection, stimulate metabolism, and relieves insomnia and depression. Sunlight is much like a nutrient on which the body depends for smooth functioning of its glandular and metabolic systems. It also acts as an important cofactor in the proper activity of vitamins in the body.[34]

Role of Rest and Exercise

Rest and properly graded exercise are important factors in the treatment of tuberculosis. When a patient recovers to full weight with no fever, he should have graded exercise to gradually adjust to considerable endurance. Deep breathing exercise should never be taken while the disease is active and considerably advanced. There is also a reported danger of tearing loose adhesions by such exercise.[35,36]

Nutrition

It is clear that TB affects nutritional status. Many patients with active TB experience severe weight loss and show signs of vitamin and mineral deficiencies. Patients with TB/Human Immunodeficiency Virus (HIV) coinfection are even worse, nutritionally. However, the evidence for best practices for nutritional management is very limited.[37]

Collapse Therapy

The main role of collapse therapy is to provide rest to the diseased part of lung and to facilitate healing. [38]

Surgery

The earlier attempts in the 1880, of removing the affected portion of the lung had been unsuccessful and resection was given up being too dangerous a procedure.[39]

Tuberculin Therapy

It was advised by Robert Koch after his discovery in 1882.

Modern Chemotherapy

It had its beginning with the discovery of streptomycin by Waksman in 1944. Soon other drugs were discovered—PAS (1948) and INH (1952) followed by rifampicin, pyrazinamide and other drugs. Standard chemotherapy with SM, INH and PAS became the right choice for the treatment of tuberculosis after the 1950. Studies conducted at Tuberculosis Research Centre (TRC), Madras (India) and other countries in 1956 had shown that domiciliary treatment with chemotherapy was as good as sanatorium treatment with chemotherapy.[40,41] Consequently, patients with pulmonary tuberculosis who were slightly active were allowed to exercise themselves in the open air.

Sanatorium Versus Home Treatment for Pulmonary Tuberculosis

Pulmonary tuberculosis is recognized at the present time as the most curable of chronic diseases. The first essential component in the treatment is to control the mental and the emotional state of the patient, without which the physical reactions cannot be controlled. To carry out these essentials, one must first be able and have an opportunity to thoroughly study the patient and his disease processes, and be able to place the patient in an environment that will assist him to the fullest extent in adjusting his psychic reactions to the circumstances.[42]

The patient in a sanatorium profits by the examples and mistakes of other patients. Education and information acquired in such an atmosphere constitute the keystone to the discipline, which is so essential in the proper treatment of pulmonary tuberculosis. In the sanatorium, the patient has a much greater opportunity to be protected from the nervous and over-anxious members of his family and the disturbances, which occur in the ordinary routines of the home.

Finally, in the sanatorium the patient learns that flare ups in the course of pulmonary tuberculosis are more or less the rule, when these occur, his reaction is entirely different from that of the patient having a similar experience in a home environment.[43-45]

SURGERY

Historically, surgery has played a major role in the treatment of pulmonary tuberculosis, while the introduction of multidrug therapy in 1970s significantly reduced its role. However, the increased prevalence of Multidrug-Resistant (MDR) TB has again renewed the interest in surgery.

Historical Procedures

The Cavernostomy Era

During 18th century, large TB cavities in the lungs were opened through the thoracic wall (cavernostomy)/ Monaldi operation.[45] Others performed “open cavernostomy” in a staged manner, which invariably caused bronchopleurocutaneous fistula which would drain.

Collapse Therapy Era

The period between 19th and 20th centuries, marked the era of bed rest and collapse therapy. Bed rest was introduced by Dettweitter in Germany and Turban in Switzerland around 1880.[46] Collapse therapy was used in 70% of sanatorium patients. The purpose of collapse therapy was relaxation of the diseased lung and a better chance for the scar tissue to contract.

Phrenic Nerve Paralysis

In the 1930s, this was the commonest procedure of lung collapse. It was supposed to help in different ways:

i. Rise of ipsilateral diaphragm reduces the distance between apex and base of lung thus relaxing the diseased portion.
ii. Decreased excursion of diaphragm provides rest to lung.

Cavities at the base of lung responded favorably to this procedure.

Artificial Pneumothorax

The use began in the late 19th century and came into wide use between 1920 and 1940. A specially designed pneumothorax apparatus was used; if there were no intrapleural adhesions, the pneumothorax relaxed the lung effectively. For cases with intrapleural adhesions, intrapleural pneumonolysis was done.

In addition, artificial pneumothorax was found to be useful in achieving culture negativity in new cases with cavitary pulmonary TB and in retreatment cases.[47]

Pneumoperitoneum

For sometime, pneumoperitoneum was used as collapse therapy by causing the elevation of diaphragm. The results of pneumoperitoneum alone were unpredictable. Combined procedure of pneumoperitoneum and phrenic nerve paralysis were often effective in the closure of a basal cavity.[48]

Extrapleural Pneumonolysis

In this procedure, a space was created between the apex of lung and the chest wall. This space was filled up with paraffin, which eventually became encapsulated with the fibrous tissue and remained in place permanently.[49]

Thoracoplasty

Alexander is considered to be the father of thoracoplasty in USA.[50] He perfected the technique of staged posterior lateral thoracoplasty with an operative mortality of less than 2% and cavity closure and sputum conversion in over 80% of cases.[50] In Plombage thoracoplasty, material substances are used to maintain collapse (Plombe), including paraffin, polythene sphere and sheets. Recently, a new modality of collapse therapy, which uses percutaneous tissue expanders (the Perthese tissue expander) has been described.[51-59]

IMMUNOTHERAPY

Anti-TB drugs are not able to fully eradicate *Mycobacterium tuberculosis* from all sites because of their relative inactivity against semidormant or persisting organisms, particularly those in lung granulomas. Several immunotherapies are being evaluated in human clinical trials as adjunctive immunotherapy together with chemotherapy having potential to:

1. Improve success rates in treatment of MDR-TB and XDR-TB
2. Shorter duration of treatment of drug susceptible TB.
3. Improve immunity
4. Reduce the pathology in individuals cured by chemotherapy thereby preventing recurrence.

Immune Protection and Immunopathology

Protective immunity is comprised of bacteriostatic and bactericidal components. Although a bacteriostatic response may transiently protect the host from an invasive pathogen, it does so at cost of creating dormancy, a source of recurrent infection, which is difficult to eradicate. Thus, the challenge for immunotherapy is to convert a predominantly bacteriostatic response into bactericidal response.

Immune protection results from phagocytosis and killing of mycobacteria by activated macrophages, this cellular response is regulated by antigen-specific T cells that produce IFN-γ, which together with TNF-α and IL-15 (refer as Type I cellular response) are essential for macrophage activation and immune protection. Other immune mechanisms that lead to bactericidal activity are autophagy, apoptosis and killing by cytotoxic T lymphocytes.

These immunoprotective mechanisms are susceptible to downregulation by combination of Th2 cytokines and TGF-β. Thus, downregulation is dependent on IL-4 expression IL-4 and TGF-β together downregulate cytotoxic T lymphocyte response. The aim of immunotherapy is to improve the immune response and to optimize the balance between Th1/Th2 immune response by downregulating Th2 response.

Immunotherapy Agents

Various immunotherapeutic agents (Table 44.2) have been used for adjunctive treatment.[60-72]

The role of some immunosuppressive agents, as well as of supplementary effect or cytokines has been also reported, but largely limited to experimental designs for the present.[73-83]

Several other agents that have been tried in the past includes the following:

i. *Pentoxifylline*[84]*:* It acts by competitive nonselective phosphodiesterase inhibition, which raises intracellular CAMP, inhibits TNFα and leukotriene synthesis and reduces inflammation and innate immunity. Combination of pentoxifylline and dexamethasone, when used to treat *M. avium* infected macrophage from normal and HIV-infected person *in vitro* showed decrease in TNFα by 48%.[84]

ii. *Imiquimod:* It is an oral inducer of IFN and other cytokines. It is a low molecular weight compound originally described as potent-inducer of IFN and other cytokines like TNF and IL-12 when given orally to mice and humans.

iii. *Transfer Factor*[85]*:* Transfer factor was first reported in 1949 by Lawrence and named it so because it was the factor that transferred tuberculosis immunity from a person who had an active immunity to tuberculosis to a naïve individual.[85] Later, it was discovered that this process in naturally accomplished between mammalian mothers and their newborns through mother's Colostrums.

Transfer factor products can be both dietary supplements and drugs depending on how they are prepared and marketed. Transfer factor preparations consist of three identifiable fractions:

- *Inducer fraction:* It triggers a general state of readiness in the immune system.
- *Antigen-specific fraction:* Is an array of critical tags used by immune system to identify the host of enemy microbes.
- *Suppressor fraction:* It keeps the immune system from focusing all its strength on a defeated infection while ignoring new microbial threat. It also control allergic reaction and block autoimmune disorder.

Originally, transfer factors were given through infection, later studies showed that transfer factor was equally effective orally.

iv. *Levamisole:* Mechanism of action for its immunostimulating effects is not well understood. It is believed that it restores cell-mediated immune function in peripheral T lymphocytes and stimulates phagocytosis by monocytes. The drug appears to restore depressed immune function rather than to stimulate response to above normal levels. Further studies are required for its effectiveness as immunomodulator in tuberculosis treatment.

Thus, immunotherapies have the potential to improve the outcome in all TB patients, including those with

TABLE 44.2: Immunoregulatory approaches for the treatment of TB

Agent	*Mechanism of action*	*Supportive studies*	*Results*
1. For which GMP manufacturing capacity exist			
i. High dose IVIg[60,61]	Anti-inflammatory action	Animal experiments	Marked therapeutic effect, and excellent safety
ii. HE2000 (16α Bromoepi-androsterone)[62]	Modified form of DHEA that cannot go into sex steroid pathway	Animal experiments	Well tolerated and safe and reduced the incidence of TB and significant decrease in viral load in HIV patient
iii. Multidose heat killed M vaccae)[63-65]	Induce regulatory T cells that inhibit Th2 response, a Th1 response that activate CTL that kill *M. tuberculosis* infected macrophages	Chinese DARDAR study	Effective as adjuctive therapy in MDR TB enhanced clearance of sputum and normalization of serum IL4 and TNFα Decrease in TB
iv. Neutralizing antibodies to IL-4 (PASCOLIZUMAB)[66]	It reduces IL-4 that causes a secondary decrease in TGFβ	Animal Experiments	Have a therapeutic effect and safe
2. For which GMP manufacturing capacity can be established			
DNA vaccine (HSP65)[67,68]	Enhance cytotoxic T cell while inhibiting IL-4 response, synergy with antibacterials with moxifloxacin	Animal experiment. Development of DNA vaccine, including three other antigens Ag 85B MPT–64 MPT–63, used together with antibac-terial	Downregulation of Th2 response. Significant reduction in CFU
3. Others			
i. Dzherelo[69]	Plant extract widely used in Ukraine	Need for definite GCP studies	
ii. SCV-07 SCICLONE (r-glutamyltryptophan)[70]	Immunostimulatory peptide with unknown mechanism of action	Small human TB study	Safe and use as an adjunct in MDR-TB, XDR-TB and in HIV-TB
iii. RUTI - A vaccine made of detoxified fragmented *Mycobacterium tuberculosis* delivered in liposome[71,72]	Trigger a strong Th1 and Th2 immunity against 13 known *M. tuberculosis* antigens. It enhances the CD8 and IFNγ	Animal experiment	In latent TB infection. It accelerates bacillary clearance

MDR-TB and XDR-TB. Immunotherapy for TB may shorten TB treatment and improve the immunity of individuals cured by chemotherapy, potentially preventing recurrence. Currently, none of the available agents have proof of efficacy for use. Further development and evaluation of existing immunotherapy agents is required to find effective agent.

TUBERCULOSIS AND NUTRITION

Introduction

Nutrition plays an important role in etiology, complications and therapy of tuberculosis. Although many are infected with tubercle bacilli, yet all do not develop the disease, tuberculosis recruits many of its candidates from amongst the undernourished, the under fed or residents of the centers of congestion of urban communities. "The death rates from tuberculosis in England rises and falls with the price of bread" was wisely said by Stewart. Young people who are both underweight and undernourished are choice of "candidates" for active tuberculosis.[86-89]

TB causes malnutrition, which further weakens immunity, thereby increasing the likelihood of active disease in latent TB. Wasting is associated with increased mortality in TB patients.[90] Reduced micronutrient intake, especially of vitamin B and minerals, such as vitamins A, E and C, zinc and selenium has been associated with impaired immune responses. [91-93]

Malnutrition and Immunity

It is well established that nutritional deficiency is associated with impaired immune functions.[94] Malnutrition limits cell-mediated immunity and increases susceptibility to infection, while infection can lead to nutritional stress and weight loss, thereby weakening the immune function and nutritional status.[95]

Malnutrition and TB

Malnutrition enhances the development of active TB, which makes malnutrition worse.[96] It has been suggested that generalized malnutrition by reducing the expression of gamma interferon, tumor necrosis factor alpha and other mycobactericidal substances may selectively compromise portions of the cell-mediated response that are important for containing and restricting TB.[97] During the wasting process, there is usually a loss of both fat and lean muscle tissue with the loss persisting for several months after the initiation of anti-TB therapy. [98,99]

During active TB, catabolic processes that cause wasting usually begin before the patient is diagnosed.[100] Utilization of amino acids and protein synthesis may be inhibited due to the presence of proinflammatory cytokines.[101,102] Cell-mediated immunity is the most important defense against TB. Malnourished individual is more likely to become infected with TB and latent infection is more likely to become active TB when the cell-mediated immune response is impaired in malnutrition.[103] In a larger study conducted in Norway, the incidence of smear- positive and smear-negative TB declined significantly with increasing BMI in all age groups.[104]

Nutritional Status Changes During TB Treatment

During drug treatment of active TB, nutritional status usually improves without supplementary nutrition. This happens due to a variety of reasons, including the improved appetite and food intake, reduced energy nutrient demands and improved metabolic efficiency. Most improvements, however are limited to increase in fat mass.[101,105,106] There are studies to show that the nutritional status may have an effect on relapse of active TB. So, the maintenance of good nutritional status in TB patients all though the life is important.

Low concentration of serum albumin less than 35 g/l, is an indicator of protein status at the time of TB diagnosis.[107] The concentration of micronutrients may have a role in host defense against TB.[92,93,95,104,108,109] In the era before drug management of active TB, administering cod liver oil rich in vitamins A and D was a common therapy to improve the host defense.[110]

Antioxidants

Antioxidants neutralize the free radicals. TB may induce oxidative substances, which in turn can promote tissue injury and inflammation. Reactive oxygen species (ROS) are highly toxic to lipids, fat cells causing peroxidation, resulting in damage to cell membranes and are also associated with the pathogenesis of lung fibrosis and dysfunction in pulmonary TB.[95,104,109,110]

Vitamin E: It protects cell membranes against lipid peroxidation and oxidative stress. Zinc is essential for DNA synthesis and cell differentiation. Zinc deficiency is associated with recurrent infection, decreased phagocytosis, decreased β and T lymphocytes production and depressed macrophage activity. Selenium is an essential part of antioxidative enzymes, such as glutathione peroxidase, which protects cells from oxidative damage.[108-111]

Studies of Micronutrient Status and TB

Vitamin A

Because of the acute phase response, serum retinal levels are generally lower in patients with active TB, particularly those who are TB/HIV coinfected and tend to improve with anti-TB therapy.[112]

Ascorbic Acid (Vitamin C)

Vitamin C, together with vitamin E and glutathione, are important for pulmonary antioxidant defense.[92,113] The levels of serum ascorbic acid in TB patients with history of smoking were significantly lower than in the controls.[92]

Pyridoxine (Vitamin B_6)

INH inhibits the phosphorylation of pyridoxine, which results in an increased excretion of vitamin B_6.[114,115]

Vitamin D

Susceptibility to TB and the severity of active TB may be increased by vitamin D deficiency.[96,97,116] It was hypothesized that immigrants from tropical countries, where latent TB is common, had a marked decrease in their serum vitamin D levels when they lived in cold and cloudy England, with considerably less opportunity for exposure to sunshine. Poverty was not considered the factor since these immigrants communities were generally prosperous.[117]

Effect of Micronutrient Supplementation on TB Outcomes

Vitamin A and zinc: The supplementation of vitamin A and zinc improves the effectiveness of the anti-TB treatment in the first-two months of therapy, with less improvement seen between two and six months of treatment. The major benefit is at the community level because the patient becomes less infectious sooner, with lesser opportunity to infect others.[118]

Anemia is common in patients with pulmonary TB, more so among TB/HIV coinfected patients.[119] However, iron loading may enhance the growth of *Mycobacterium tuberculosis* by impairing macrophage suppression of invading microorganisms. Elevated dietary iron may increase the risk of activating TB disease. In mild to moderately anemic TB patients, iron supplementation accelerated the normal hematopoiesis.[120]

Malnutrition and TB/HIV Coinfection in Adults

Coinfection may lead to poor appetite with decreased nutrient intake, which may interact with the altered metabolism associated with both infections as part of the immune and inflammatory responses.[94,119] The combination of TB/HIV coinfection and malnutrition has been termed "triple trouble". [120]

Nutritional Support within TB Programs

Food assistance is a potentially influential targeted means for increasing adherence to TB treatment, reducing the costs to patients of staying in treatment and improving the nutritional status. Food assistance may influence early case detection and promote full course of treatment. Both of these are important to decrease TB transmission.[121,122]

World Food Program (WFP): The goal of WFP is to improve nutrition, quality of life and self help of individual and communities.[94]

C-SAFE: The Consortium for the Southern Africa Food Security Emergency (C-SAFE) provides food assistance to patients with HIV/Acquired Immunodeficiency Syndrome (AIDS), including those coinfected with TB.[114]

Dietary Management in TB Patients

A TB patient requires more food for two reasons: First he has fever, which causes him to burn up his energy faster than in health. Second, he has a destructive process going on in his body, which he must seek to overcome by supplying ample repair material in the form of food.[86] A highly publicized diet is the Hermannsdörfer-Sauerbruch diet for tuberculosis given at the ratio of 1.15 gm protein, 2.7 grams fat; 4 grams carbohydrates.[86] Most TB patients have poor appetite, therefore, a meal should be made simple, easily digestable and tempting to encourage the patient to eat. All meals should have cereal-pulse combination with some amount of animal proteins. Some typical examples are: "Khichri" with curd; sweet dalia with milk; "paushtic chapattis" with curd and cheap sources of vitamin C, such as guava, amla, sprouted pulses should be given.[88]

A day's simple diet plan for TB patients (Tables 44.3 and 44.4) should be able to provide: Energy = 2,787 kcal; protein = 75 to 90 grams; vitamin A = 600 mg retinal; and calcium = 400 mg.

REHABILITATION IN TUBERCULOSIS

For many persons with tuberculosis, microbiological cure is just the beginning, not the end of their illness. Post-tuberculosis pulmonary impairment has emerged as a distinct clinical entity, which is almost indistinguishable from other forms.[122,123] Cavitation, extensive fibrosis, bulla formation and bronchiectasis have been implicated in the genesis of COPD caused by the destroyed lung.[124-126] A definite association between the type of healed lesions present and degree of impairment exist.[127] Pathological changes, such as "emphysematous change" on the radiograph could be considered as an important cause of obstructive ventilatory impairment. Effective chemotherapy decreases the likelihood of development of obstructive lung diseases.[128]

Lung function, such as Forced Vital Capacity (FVC) and post bronchodilator FEV_1 of post-tuberculosis patients were lower compared to those of COPD.[129] Thus,

TABLE 44.3: Food plan for tuberculosis patients in India

Meal	*Menu*	*Amount*
Early morning	Tea	1 cup
Breakfast	"Paushtic chapattis" (Besan, spinach, cabbage, onion, wheat, flour and oil)	2
	Curd	95 grams
	Tea	1 cup
Mid morning	Sprouted "moong chat"	1 bowl
	Tea	1 cup
Lunch	Scrambled egg	1
	Spinach and potato, vegetable	1 bowl
	"Chapattis"	2-3
	Peanut "chikki"	
	Amla	1
Evening tea	Tea	1 cup
Dinner	"Upma" (with vegetable)	1 bowl
	"Sâmbhar" (with brinjal and bottle gourd)	1 bowl
	Carrot "raita"	1.5 bowl
	Rice/ "chapattis"	cooked/2 to 3
	Guava	1

TABLE 44.4: Food choices for inclusion in a meal

Foods high in vitamin B_6 (pyridoxine): • Liver, chicken, meats, fish • Dried fruit (raisins, dates, figs) • Hazelnuts, walnuts, peanuts • Brussels sprouts, cauliflower, peas, broccoli • Chick peas, soybeans • Wheat germ, whole grain cereals, oatmeal • Bananas, cantaloupe, grapes	Foods high in iron: • Liver, kidney • Cream of wheat, whole grain cereals • Meats, veal, ham • Dried peas, beans and lentils • Prune juice, prunes, dates, dark green leafy vegetables Tip: Iron is taken up by the body best when eaten with foods high in vitamin C
Foods high in vitamin A: • Broccoli, carrots, squash, sweet potatoes • Spinach and other dark green leaf vegetables • Liver, dairy products, eggs • Cantaloupe, apricots	High protein foods: • Meats, lamb, veal, ham • Milk, yogurt, cheese • Poultry and fish • Dried peas, beans and lentils • Eggs Tip: Add skim milk powder to soups, milk and casseroles
Foods high in vitamin C: • Citrus fruit and juice • Tomato, baked potatoes • Broccoli, sweet peppers, kale • Cantaloupe, strawberries, cabbage, cauliflower Tip: Steam or cook vegetables in a small amount of water just until tender-crisp, will help to get the most amount of vitamin C from the vegetables.	Foods high in calcium: • Milk, yogurt, and cheese • Soyabeans, tofu • Broccoli, kale • Sardines and salmon with bones • Baked beans (canned)

pulmonary impairment associated with obstructive airway disease is recognized as a common complication of advanced tuberculosis. There is need of rehabilitation in patient of tuberculosis for the restoration of the disabled to maximum physical, mental, social, economic and vocational capacity of which they are capable.

Situation Needing Rehabilitation of TB Patients

- Chronically ill and drug failure patients, who continue to excrete TB bacilli inspite of treatment.
- Those patients, who have no source of steady income.
- Development of complication like emphysema, bronchiectasis or whose lung functions following surgical intervention is reduced to very low.

Tuberculosis continues to afflict the low-income groups. By the time they seek diagnosis and treatment, the disease is already in the advanced stage. Very often, they become untreatable and secrete drug-resistant bacilli. Some of them have little possibility of returning to work. Joint family system is fast disintegrating in India, but longevity is increasing. People have to rely on their own resources. Other members of the family are reluctant to bear the burden of the incapacitated person. There is thus, need for organized rehabilitation in these situations. Settlements and colonies for such handicapped people were established in the past. Papworth and Preston Hall in the United Kingdom, a township in Saranac Lake round the famous Trudeau Sanatorium in USA and Sheltered Work Centers like Altro shops in New York are some examples.

Rehabilitation is a field in which the Tuberculosis Association of India, other voluntary organizations and social service agencies can play an important role with the help of state governments and the Government of India.

Prevention of Tuberculosis

Rajesh N Solanki, Ghanshyam B Borisagar, Jitendra A Sisodia

INTRODUCTION

Tuberculosis (TB) is endemic in many countries, including in India. Unsuspected TB cases contribute to TB transmission because they go unsuspected for days or weeks altogether. As soon as it gets detected, the patient should immediately visit a multiple health care facility or be admitted indoors in the wards. Unless TB is diagnosed (or at least suspected), its proper treatment and proper infection control measures are not put in place. In a community or a group with a high burden of disease, it is the responsibility of public health officials, to put preventive measures in place to alleviate the burden. There are multiple levels of prevention that are crucial in decreasing the mortality and morbidity of a disease: Primordial, primary, secondary and tertiary prevention.[1]

PRIMORDIAL PREVENTION

Adoption of proper lifestyle, especially in the early childhood is the basis of primordial prevention. For TB, it will involve the following measures:

- Nutritional interventions
- Environmental modifications (especially healthful housing and proper sanitation)
- Appropriate health education and behavioral changes.

PRIMARY PREVENTION

Primary prevention efforts aim at reducing an individual's susceptibility to the disease, illness or injury. Education, changes in lifestyle and behavior modification are components of primary prevention. Tuberculosis is infectious when it occurs in the lungs or larynx. TB that occurs elsewhere in the body in isolation is usually not infectious. A person who has TB disease in his/her lungs or larynx, can release many tiny particles called droplet nuclei into the air by coughing or sneezing; smaller numbers of droplet nuclei are released during normal activities like talking or spontaneously during breathing. Approximately 5,000 droplets are produced while talking, which may be increased four-fold or higher during coughing. These droplet nuclei particles are invisible to the naked eyes and approximately 1 to 5 microns in size. Droplet nuclei can remain airborne inside the room air for a long period of time, until they are removed by natural or mechanical ventilation or by exposure to direct sun light, which kills the *Mycobacterium* very fast.

Administrative Measures

The first line of defense for preventing the spread of TB in health care settings is to apply administrative control measures, which have greater impact on preventing TB transmission in health care setting. The aim of administrative interventions in any health care facility that manages patients with suspected tuberculosis is to reduce the total time period that such a patient stays in the health care facility, and reduce airborne transmission to other patients and health care workers in this limited time period.

Outpatient Area

Patients of TB, like any other patient, have to wait for long periods before they are actually examined by the physician. During this period, these patients are a constant source for airborne spread of disease to others. Reducing the overall stay of such patients in the health care facility is likely to prove the single-most effective measure of reducing airborne disease transmission in these areas. This can be achieved by fast tracking these patients, which can be accomplished by several measures that are not mutually exclusive. Fast-tracking will also depend upon the type of health care facility. At a chest center/hospital, most patients are chest symptomatics where fast-tracking has no real application, but the process will be more useful for general hospitals.

Inpatient Care Facilities

Need-based hospitalization of TB patients: One of the most effective means to reduce the risk of transmission of airborne pathogens, such as *M. tuberculosis* in hospital settings is to manage such patients in the outpatient setting whenever possible. Many patients can be managed entirely as outpatients, thereby avoiding hospitalization and the risk of exposing other patients and staff.

Establish separate rooms, wards or areas within wards for patients with infectious respiratory diseases: When hospitalization is required, TB patients should be physically separated from other patients so that others are not exposed to the infectious droplet nuclei that they generate. Policies on TB patients, separation inevitably generate concern about stigma, but with appropriate measures, such as training and public posting of separation rules helps to minimize stigma.

Administrative procedures should ensure that separation happens promptly, similar to the separation of men and women during inpatient admission. If sputum-smear microscopy or other relevant diagnostic tests are performed for patients with respiratory symptoms at the time of admission, then those who are smear-positive TB can be quickly identified for separation from other patients. Priorities for separation of TB patients are as follows:

- Separation of sputum-smear positive TB patients from immune compromised patients
- Separation of patients with known or suspected drug-resistant TB from immune compromised patients
- Separation of patients with known or suspected TB from all other patients.

The best choice for infectious or potentially infectious patients is to manage them in isolation rooms. Where such isolation rooms are not feasible, other options for physical separation include:

- Having a few small "airborne precaution rooms" for patients with infectious respiratory disease patients
- Having a separate ward designated for patients with infectious respiratory disease
- Keeping a designated area with better ventilation available for the placement of potentially-infectious patients
- When it is not possible to have a designated airborne precaution room, or area of a ward, there can at least be a designated area where TB inpatients can be preferentially placed.

Cough hygiene and adequate sputum disposal: Tuberculosis or multidrug resistant tuberculosis (MDR-TB) wards having infectious patients should display sign boards in the ward demonstrating cough hygiene. All patients admitted in the ward/area should be issued surgical masks and counseled on their proper use. Adequate measures for safe collection and disposal of sputum should also be undertaken.

Establish safe radiology procedures for patients with infectious respiratory disease, including smear-positive TB cases or TB suspects: When caring for an infectious TB case/suspect, the radiology departments should attempt to:

- Schedule inpatient chest radiographs on infectious and suspect TB patients for non-busy times, such as the end of the afternoon
- Provide coughing patients with a surgical mask to wear, or tissues or cloth to cover their mouths
- Provide priority service to potentially infectious TB patients to minimize the length of time spent in the department
- Restrict access to the radiology suite to patients and essential personnel only
- Use the room with the best ventilation for taking images of potentially infectious TB patients.

Environmental Controls

Environmental control measures are the second line of defense for preventing the spread of TB in health care settings. Environmental controls include ventilation (natural and mechanical), ultraviolet germicidal irradiation (UVGI), filtration and other methods of air cleaning. Environmental controls work on the same basic principle—dilution of infectious particles through real or "effective" air exchange. (One air change has occurred when the volume of air entering or exiting a room is equal to the volume of the room).

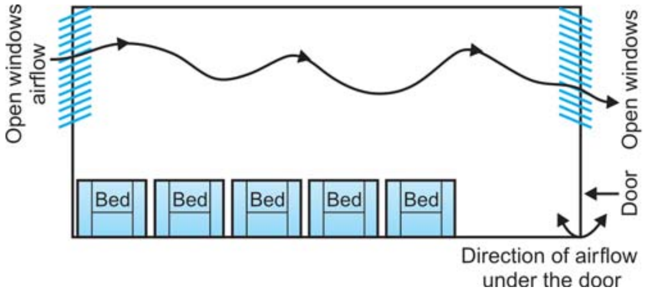

Fig. 45.1: Schema of a room with natural ventilation—Fixed unrestricted openings on both sides allow for adequate air exchange

Ventilation

In the case of ventilation, the dilution occurs through the introduction of fresh, uninfected air and removal of the infected air.

Natural ventilation: It refers to fresh air that enters and leaves a room or other area though openings such as windows or doors (Fig. 45.1). Natural ventilation is "controlled" when openings are fixed and unrestricted to maintain airflow at all times. Unrestricted openings (i.e. those that cannot be closed) on opposite sides of a room provide the most effective natural ventilation. In existing health care facilities that have natural ventilation, when possible, effective ventilation should be achieved by proper operation and maintenance of openings, and by regular checks to see that openings remain free of obstruction at all times.

Simple natural ventilation can be optimized by maximizing the size of the windows, opening up fixed window panes, by locating windows on opposing walls, and by the use of propeller "mixing fans". Types of mixing fans include ceiling fans, stand/desk mounted fans, or window/exhaust fans located in open windows. Mixing of air can disperse the pockets of high concentrations, such as in the vicinity of patients. The total number of infectious particles in the room will not change with mixing; the concentration of particles near the source may be reduced, and the concentration in other parts of the room may increase. In other words, unless adequate ventilation is present the mixing fan will not be useful in reducing infectious particles and the risk of transmission.

A common problem with reliance on natural ventilation is that patients or staff members close the windows during cold weather or at night. Further, there is likely to be variability of airflow patterns due to varying weather. In colder climates where rooms are closed to keep temperature adequately high especially in winter, natural ventilation can be implemented by airing via windows at frequent intervals. If natural ventilation of the room is inadequate, additional mechanical ventilation or other measures may be needed, especially in areas where risk of *M. tuberculosis* transmission is high.

Mechanical ventilation: It uses fans to drive the airflow through a building. Mechanical ventilation can be fully-controlled and combined with air conditioning and filtration systems as is normally done in some office buildings. Mechanical ventilation also includes "Mixed mode ventilation", in which exhaust and/or supply fans are used in combination with natural ventilation to obtain adequate dilution when sufficient ventilation rate cannot be achieved by natural ventilation alone.

The simplest form of mechanical ventilation is the use of "exhaust fans", placed for instance in windows to move air from inside a room to the outdoors. Exhaust fans also may be more acceptable to staff and patients than keeping windows consistently open. If exhaust fans are used, it is important to ensure that airflow is adequate, and airflows across the room (not in and out the same window or vent), and that exhaust fans and air intake (vents) should not be located side by side to avoid short-circuiting of air.

National Standards for Minimum Ventilation in Health Care Settings

Health care facilities should maintain a minimum amount of ventilation during all climatic conditions. This can be achieved by the fixed number of Air Changes per Hour (ACH). In settings relying on mechanical ventilation (either fan-assisted or closed systems) this can be calculated with the assistance of local engineers (Table 45.1).

Where ACH is not possible to measure, as is usually the case in rooms with natural ventilation

The following standards for ventilation should be followed to ensure that air exchange is safely greater than 12 ACH under all climactic conditions.

- Natural ventilation should be "controlled", with fixed, unrestricted openings that are insensitive to climatic conditions
- Openings should constitute greater than 20% of floor area
- Openings should be there on both the sides, preferably on opposite sides. For example, a 100 square feet, room should have greater than 10 square feet fixed, unrestricted openings on both sides, total of 20 square feet.

TABLE 45.1: Minimum air-changes per hour required for various health care settings

Type of health care setting	*Minimum air-changes per hour (ACH)*
Registration areas	>6 ACH[*]
Outpatient departments and their waiting areas	>6 ACH
Inpatients departments	>6 ACH
High-risk settings and their waiting areas	
ART centers	
TB/Chest departments (outpatient and inpatient)	
Bronchoscopy procedure rooms	>12 ACH[†]
MDR-TB wards and clinics	
Airborne isolation rooms	

[*] Equivalent to >40 liters/second (l/s) for a 4 m × 2 m × 3 m = (24 m^3) room.

[†] Equivalent to >80 l/s for a 4 m × 2 m × 3 m = (24 m^3) room.

Ultraviolet Germicidal Irradiation (UVGI)

Mycobacterium tuberculosis (MTB) is sensitive to germicidal radiation of ultraviolet rays found in the UV-C portion of the ultraviolet spectrum. The use of UVGI lamps is reserved for high-risk areas (laboratory, sputum collection area, poorly-ventilated spaces, etc.), where other environmental measures are not sufficient due to climatic or structural constraints.

Sputum collection area: This area must be settled outside in open air where bacilli will naturally be dispersed by wind and killed by sun rather than in a closed room where the concentration of bacilli will be high. In cold regions, assign a specific room of small size (1 m) with one single glass door to opening outside. Keep the door largely open for five minutes between each patient. The small volume of air in this room facilitates rapid ventilation.

Constraints on the use of UV lamps:

- Monthly checking and daily maintenance (dusting)
- Risk of mercury poisoning in case of broken or mishandled lamp; disposal of mercury from used lamps requires specific procedures
- May not work in humid areas.

Need to be replaced every 5,000 hours (as they begin to emit harmful wavelengths of light. A lamp working eight hours per day must be replaced every six months).Use only lamp-type UVC-254 µm, made from mercury and quartz

- Use only indirect lamps (portable lamps or those mounted high up and directed toward the ceiling), to avoid possible burns to the conjunctiva or skin from direct exposure. Ensure that the airflow crosses in front of the lamp
- Use direct UV lamps in empty rooms only (they can be switched on at night).

Personal Protection

Health staff: Tuberculosis is transmitted mainly via the respiratory route. Only anti-inhalation masks (high-filtration masks) are capable of preventing inhalation of the bacillus.

All members of the staff must wear these masks, whether caregiver or not under following conditions:

- When in contact with contagious patients
- When collecting sputum samples and preparing slides
- When collecting and disposing the sputum containers.

Patients and attendants: Contagious patients must wear a surgical mask (anti-projection mask) when they leave their rooms to go to another department or any other enclosed area (except outdoors). The mask is intended to prevent projection of *M. tuberculosis* by the carrier. Attendants and visitors must wear a high-filtration mask (like that worn by staff), when entering a contagious TB patient’s room. Inform patients, visitors and attendants about the risk of TB transmission and how to avoid it, or protect themselves: Ask patients to cover their nose and mouth when they cough or sneeze, and to use a sputum container; explain why, when and how to use masks; display posters of protective measures inwards, waiting rooms, etc.

Patient, visitor and attendants’ movement: Inside the TB department, circulation of patients and attendants should be controlled as follows:

- Limit the number of visits, duration of each visit, particularly for contagious patients
- Encourage visits outside the building, in the open air
- Before any visit, the nurse should provide information on the transmission risk.

In addition to wearing a mask, which is a specific protective measure, standard precautions (hand hygiene, gown, etc.) apply in TB wards, just as they do in any other hospital department.

Vaccines

The only vaccination for TB in the market is the Bacillus Calmette-Guérin (BCG) vaccine.[2] It has poor efficacy ranging from 0 to 80%. The BCG vaccine is routinely given in India to the newborn after birth. It is not recommended in the United States because secondary prevention techniques are greatly hindered by the BCG vaccine, which can interfere with the management of persons who are possibly infected with *M. tuberculosis*.

SECONDARY PREVENTION

Screening

Secondary prevention denotes the identification of people who have already developed a disease, at an early stage in the disease's natural history, through screening and early intervention. One can identify disease at the earliest stage, in its natural history. Hence, making intervention measures more effective. One can therefore, prevent mortality or complications of the disease and use less invasive or less costly treatment to do so.

Screening tests and preventive therapy accomplish secondary prevention efforts. This is particularly important for high risk population groups such as the Health care workers (HCW), prisoners and inmates of common living facilities.[3-5] Implementation of preventive therapy (treatment with antituberculosis drugs) reduces the risk that TB infection will progress to TB disease. Early identification and successful treatment of persons with TB disease remains the most effective means of preventing disease transmission.[6] Therefore, people who are likely to have infectious TB should be identified and provided treatment before they are able to widely transmit the *Mycobacterium*. Some of the screening methods applied for identification of high risk group populations are as given below:

Symptomatic Screening

Whenever possible, health care workers should undergo the initial screening. During their initial medical screening, they should be asked if they have a history of TB disease or if they have been treated for Latent tuberculosis infection (LTBI) or TB disease, previously. Documentation of any such history should be obtained from medical records, if possible. They should be observed for the presence of a cough or evidence of significant weight loss. All new recruits/inmates should be immediately screened for the symptoms of pulmonary TB. The index of suspicion should be high when pulmonary symptoms are accompanied by general, systemic symptoms of TB (e.g. fever, chills, night sweats, easy fatigability, loss of appetite and weight loss). Individuals, who have symptoms suggestive of TB disease should immediately receive a thorough medical evaluation, including a Tuberculin Skin Test (TST) or QuantiFERON-TB Gold (QFT-G), a chest radiograph, and if indicated, sputum examinations. Symptom screening alone is an unsatisfactory mechanism for TB, except in facilities with a minimal risk for TB transmission.

Chest Radiograph Screening

Screening with chest radiographs can be an effective means of detecting new cases of unsuspected TB disease. Radiographic screening requires fewer subsequent visits than a TST (i.e. only those with suspicious radiographs or TB symptoms require follow-up). However, such screening will not identify people with LTBI. Screening inmates with a chest radiograph doubled the TB case-finding rate and reduced the time from intake into the correctional facility to isolation substantially compared with TST testing (2.3 days and 7.5 days, respectively).[5] Digital radiographs (miniature or full size) provide enhanced imaging and improved storage and readability. A miniature radiograph can be performed in less than 1 minute and exposes the patient to approximately one-tenth the radiation dose of a conventional radiograph.

Screening with chest radiographs might be appropriate in certain jails and detention facilities that house substantial numbers of inmates for short periods and serve populations at high risk for TB (e.g. those with high prevalence of Human immunodeficiency virus (HIV) infection or history of injection-drug use and foreign-born persons from countries in which TB prevalence is high). Inmates who are infected with HIV might be anergic and consequently, might have false-negative TST results. Chest radiograph should be a part of the initial screening of HIV-infected patients and those who are at risk for HIV infection, but whose status is unknown. Persons who have radiographs suggestive of TB, should be isolated and evaluated further. Sputum-smear and culture examinations should be performed for inmates, whose chest radiographs are consistent with TB disease and it might be indicated for at least certain persons who are symptomatic, regardless of their TST, QFT-G or chest radiograph results.

Detection of Latent Tuberculosis Infection

The centers for disease control and prevention (CDC) recommends a strategy to identify those who have LTBI and, if indicated, the use of chemotherapy to prevent the latent infection from progressing to active TB disease. There are two tests that can be used to help detect LTBI.

a. *Tuberculin skin test:* Tuberculin skin testing using 0.1 ml of 5 tuberculin units (TU) of Purified protein derivative (PPD), tuberculin, is the most common method of testing for TB infection. In this test tuberculin is injected intradermally to see if there is a reaction to the test. Persons who have a documented history of a positive TST result, a documented history of TB disease, or a reported history of a severe necrotic reaction to tuberculin should be exempted from a routine TST. The TST sensitivity ranges from 75 to 90%.[7,8] Despite this limitation, skin testing, along with symptom review, frequently constitutes the most practical approach to screening for the TB disease.

b. *QuantiFERON-TB gold:* QFT-G is more sensitive than the TST. The test is highly specific and unaffected by BCG vaccination status, a major cause of false-positive TST response.

Chemoprophylaxis

Chemoprophylaxis is most often the treatment for primary infection in order to sterilize the lesions and prevent the development of active TB. It is more a treatment than chemoprophylaxis, in the literal sense of the term. It may reduce the risk of developing TB by up to 90% in a patient with primary infection. It usually consists of daily administration of isoniazid (INH) 5 mg/kg (maximum 300 mg/day) for six months, in both children and adults. The effectiveness of isoniazid prophylaxis depends on the sensitivity to isoniazid. The use of isoniazid is contraindicated in patients with severe or chronic active hepatitis. It should be administered with caution to patients who regularly consume alcohol.

i. *Chemoprophylaxis for newborn infant of sputum smear-positive mother:* In all the cases, where the mother is sputum smear-positive, at birth of child, chemoprophylaxis is administered to the child for six months; BCG vaccination is done afterwards (BCG vaccine should not be given during administration of isoniazid).

If a child immediately or subsequently develops signs of TB (in general, only evident after approximately two to eight weeks: Arrested growth, splenohepatomegaly, jaundice, sometimes pneumonia), she/he should receive complete anti-TB treatment after exclusion of other possible medical causes.

If a tuberculin skin test is possible, the approach is to administer isoniazid for three months, then do a tuberculin skin test.

If the tuberculin skin test is positive, isoniazid is continued for three more months.

If the tuberculin skin test is negative, stop isoniazid and administer the BCG vaccine.

- The child should not be separated from her/his mother unless she/he is severely ill. Breastfeeding should be continued. It is possible that isoniazid is not effective if primary resistance against this drug exists (varies according to the area) or if there is a problem of secondary resistance in the mother. The child must, therefore, be closely monitored in all cases.
- If a mother presents with TB during pregnancy or if the sputum becomes negative under treatment, it is sufficient to vaccinate the child at birth and to monitor him/her thereafter.

ii. *Children under five years of age in contact with Mantoux positive patients:* If suspicion of TB exists before administering chemoprophylaxis it is imperative to rule out active TB. If TB is suspected, the child should undergo complete curative treatment. If not, prophylaxis should be administered for six months. If the child is healthy, administer chemoprophylaxis for six months, regardless of the vaccination status of the child. If it is not possible to administer the prophylaxis, vaccinate and monitor the child.

The use of a tuberculin skin test may help to better specify indications for prophylaxis. In practice, it is simpler and prudent to systematically administer prophylaxis, when indicated.

iii. *Chemoprophylaxis in HIV patient:* The use of ART in HIV patients is the best TB prophylaxis, with up to 80% of risk reduction, without the use of isoniazid. The target population for chemoprophylaxis among HIV-seropositive includes all Mantoux (PPD) positive individuals who do not have active tuberculosis and could include PPD negative individuals living in high prevalence region for TB.

The optimal duration of preventive therapy with single drug isoniazid, daily or twice weekly, should be greater than six months to provide the maximum degree of protection against tuberculosis. The effectiveness of preventive therapy should be evaluated at regular intervals by monitoring patients for drug adherence, drug toxicity and for the development of tuberculosis. Though the impact of preventive therapy on an individual basis may be rather small, widespread implementation would have substantial impact on morbidity due to tuberculosis and some impact on mortality. Preventive therapy should be offered at voluntary counseling and testing centers, as part of a package of care that includes prophylaxis and treatment of opportunistic infections, nutritional support and counseling.

The CDC has recommended that preventive therapy for anergic HIV-infected persons should be considered if the patient has had known contact with an active TB case or belongs to a group in which the prevalence of TB infection is high.[9] In areas endemic for TB and HIV, Purified protein derivative (PPD) or tuberculin test may not be helpful in identifying persons who could benefit from INH prophylaxis. Among TB patients with HIV infection, up to 40% could be anergic. This further complicates the issue of tuberculosis preventive therapy among individuals infected with HIV.

Chemoprophylaxis in tuberculin negative HIV infected persons: Tuberculin skin test negative, HIV infected persons from high risk groups or from areas with a high prevalence of *M. tuberculosis* infection may be at increased risk of primary or reactivation tuberculosis. Combining the various studies on efficacy of preventive therapy in subjects with a negative PPD test, INH was found to be significantly better than placebo. Hence in HIV seropositive individuals, living in a high prevalence TB region, with negative PPD or in situations where tuberculin test cannot be performed, chemoprophylaxis with INH will reduce the risk of developing active TB in the short-term to around 60% of what it would have been without such a treatment.

Prerequisite to initiate preventive therapy: Prior to starting an individual on preventive treatment for tuberculosis, it is essential to ensure that he/she does not have active tuberculosis. This is done by a complete clinical examination along with a chest X-ray and sputum smear examination for Acid-fast bacilli (AFB). It is advisable that chest X-ray is done for every individual before considering preventive therapy. Any HIV-infected patient with fever, cough or abnormal chest X-ray should not be given preventive treatment until a full evaluation is done to confirm that active TB disease is not present. At times, it is difficult to exclude TB even when the chest radiograph is normal and three sputum smears are negative for AFB. Where mycobacterial culture facilities are available, sputum culture can be used to definitively diagnose TB. In general, it is safe to presume that completely asymptomatic individuals are unlikely to have TB.

Duration of preventive therapy: A multicentric trial conducted in USA, Mexico, Brazil and Haiti, demonstrated that the magnitude of protection obtained from a regimen of isoniazid (H) administered daily for 12 months was similar to that obtained from a regimen of rifampicin (R) and pyrazinamide (Z) administered daily for two months.[10] Moreover, it was noted that persons taking R and Z for two months were significantly more likely (80%) to complete therapy than those taking H for 12 months (69%). However, due to several cases of fatal hepatotoxicity reported among HIV-negative individuals on the RZ regimen, it is no longer recommended for preventive therapy.

There is evidence to suggest that preventive therapy is efficacious in HIV positive persons with tuberculin reactions greater than 5 mm, and that optimal duration of isoniazid preventive therapy (using a single drug) should be greater than six months to provide the maximum degree of protection against TB. Although the American Thoracic Society has recommended that isoniazid therapy should be continued for 12 months in persons with HIV infection, there are only a few studies comparing the efficacy of this approach with that of either shorter or longer courses.[11]

a. *Chemoprophylaxis in special situations:* Chemoprophylaxis in pregnancy: Chemoprophylaxis for tuberculosis is recommended during pregnancy for HIV-infected women, who have a history of exposure to active tuberculosis or after active TB has been ruled out. INH with pyridoxine (to reduce the risk of neurotoxicity) is the prophylactic agent of choice.[12] Some may choose to initiate prophylaxis after the first trimester to avoid teratogenicity.

   Chemoprophylaxis in children: Infants born to HIV-infected mothers should have a Mantoux test (5-TU PPD or 1-TU PPD RT23 with Tween 80) at or before age of 9 to 12 months, should be retested at least every 2 to 3 years.[12] Children exposed to those with active TB, should be administered preventive therapy after active TB has been ruled out. However, there have been no clinical trials of preventive therapy in HIV-positive children.

b. *Secondary prophylaxis:* The rate of recurrent TB is higher in HIV-1 positive individuals than in HIV-negative individuals with both reactivation and new infections contributing to recurrences.[13] It also showed that the absolute impact of secondary preventive therapy to reduce TB recurrence was highest among the individuals with low CD4 cell counts.

Current recommendations for preventive therapy against TB in HIV infected persons: WHO recommendation: Isoniazid is recommended drug (5 mg/kg to maximum 300 mg) to be taken daily, as self-administered therapy for six months. Individuals should be seen monthly and given only one month's supply of medication at each visit.

CDC recommendation: Isoniazid is chosen for prevention of tuberculosis in persons with HIV Infection. It is recommended for nine months rather than six months of rifampicin. Pyrazinamide may be offered daily for two months to contacts of patients with INH resistant, rifampicin susceptible TB.

American Thoracic Society: Isoniazid is recommended for 12 months as prophylaxis in person infected with HIV infection.[14]

iv. *Chemoprophylaxis and MDR-TB:* Among contacts of patients with MDR-TB, the use of INH is questionable.[15] Although alternative prophylaxis treatments have been suggested, there is no consensus regarding the choice of the drug(s) and the duration of treatment. Prompt treatment of MDR-TB is the most effective way of preventing the spread of infection to others. The following measures should be taken to prevent spread of MDR-TB disease:

- Early diagnosis and appropriate treatment of MDR-TB cases
- Screening of contacts as per Revised National Tuberculosis Control Programme (RNTCP) guidelines
- Further research into effective and nontoxic chemoprophylaxis in areas of high MDR-TB prevalence.

TERTIARY PREVENTION

The treatment of people who have already developed a disease is often described as tertiary prevention. The final strategy used for preventing and controlling TB is the identification and treatment of patients with active TB. An individual with active TB is infectious. Special precautions or isolation may be necessary to avoid transmission to others. Once the individual begins treatment and continues to follow the prescribed regimen, the individual becomes usually noninfectious within days or weeks.

BCG Vaccine

PT James

INTRODUCTION

BCG vaccine is a live attenuated vaccine developed from a strain of *Mycobacterium bovis*. The vaccine is known after Albert Calmette, a bacteriologist and Camille Guérin, a veterinarian of Pasteur Institute. BCG vaccine has existed for more than 80 years and it is the most widely used amongst all current vaccines. It is administered to most of the neonates and infants in countries where it is part of the National Childhood Immunization Programme. More than three million doses of the vaccine have been used worldwide.[1]

History of BCG

Calmette and Guèrin while working at the Pasteur Institute, Paris were involved in the subculturing virulent strains of tubercle bacilli and testing different culture media. On seeing that a glycerine-bile-potato mixture grew bacilli that seemed less virulent, they changed the course of their research to see if repeated subculturing would produce a strain that could be attenuated for use as a vaccine. They started their experiment in 1908 to attenuate a virulent bovine strain of *Mycobacterium tuberculosis*. The strain was subcultured repeatedly every three weeks in media containing glycerin and ox-bile. Over a period of 13 years, 231 subcultures were made and finally the strain became attenuated, proved incapable of producing disease and not able to revert to its original virulence.[1]

Vaccination with BCG started from 1921 onwards. To begin with, it was administered orally and later, intradermally. In 1930, 251 infants were given BCG by mouth during the first 10 days of life in the Hanseatic city of Lübeck in Germany. Of them, 72 died of tuberculosis, most of them within two to five months. In addition, 135 developed tuberculosis, but eventually recovered; 44 became tuberculin positive, but remained well. There was an uproar against BCG all over the world. It was subsequently discovered that the BCG administered had been contaminated with a virulent strain that was being stored in the same incubator, which led to legal action being taken against the manufacturers of BCG. The incharge of the Lübeck laboratory was sentenced for 2 years imprisonment. Even though, BCG was exonerated from this disaster, the incident did cause a bad reputation for the vaccine. The value of BCG was re-established in 1928 by the Health Committee of League of Nations.

In most of the countries, vaccination is recommended for children and it is compulsory in many of them. In USA, BCG vaccination is not recommended routinely except in special circumstances, such as for those children exposed to multidrug-resistant tuberculosis. In UK, BCG is still given to school children, aged 13-14 years of age who show less than 5 mm in duration on tuberculin testing.[2]

In developing countries with the high incidence of tuberculosis, BCG is recommended to neonates at birth or as early as possible. In India, BCG was introduced in 1948 as a pilot project in two centers. In 1949, it was extended to schools in almost all the states in India. Dr Frimodt Moller had introduced BCG in Madanapalle under the aegis of International Tuberculosis campaign. A BCG-vaccine production center was established in Guindy, Madras in 1948 with the support of UNICEF and WHO.[3]

The Vaccine

BCG vaccine is available in two forms—liquid form and freeze-dried form (lyophilized). The liquid vaccine has to be freshly prepared and used within 14 days. Freeze-dried form can be stored for longer periods when kept below 6°C. All BCG strains in the world are derived from the original strain maintained at the Pasteur Institute, Paris. For vaccine production, a seed lot system is maintained to minimize the variation, which may occur on the repeated subculturing of the strain. The bacterial strain in the uniform composition is maintained in the dried form and stored below 6°C. Culture material for vaccine production is taken from this seed lot. All BCG laboratories keep their strains in the freeze dried form to prevent these strains from reverting back to their virulent forms.

The common strains used for vaccine production are Pasteur 1173pz, Tokyo 172, Danish 1331 and Glaxo 1077. In India, Danish 809 was used earlier, but later Danish 1331 is being used for both liquid and freeze-dried vaccine production. BCG Laboratory, Guindy, manufactures freeze-dried BCG vaccines. The vaccine was available initially in 50 dose ampoules, later changed to 20 dose ampoules in order to avoid wastage.[4] The Staten Serum Institute, Copenhagen used to supply BCG seed to the Madras laboratory, but later in 1993, Madras laboratory prepared their own seed lot, the Madras Working Seed Lot (MWSL). The initial capacity of the laboratory was 40 million doses when the country needed 55-60 million doses. From 2,000 onwards, India is self-sufficient in vaccine production and even capable of exporting it.

Vaccination

BCG is administered as intradermal injection at the lower deltoid area, because the site has the lowest complication rate. The dose is 0.1 ml for children and 0.05 ml for infants below 3 months old; 0.1 ml vaccine contains 0.1 mg of moist weight of BCG.

BCG vaccine can be adversely affected by exposure to light, so it should be stored in the dark except when the doses are actually being withdrawn from the vial.[5] The vaccine should be used immediately after reconstitution, any reconstituted vaccine not used within eight hours must be discarded. Any reconstituted product, which exhibits flocculation or clumping that cannot be dispersed with gentle shaking, should not be used. The reconstituted vaccine should be maintained at 2 to 8°C (35 to 46°F). BCG vaccine (Freeze-dried) contains viable attenuated mycobacteria and should be handled as an infectious agent at all times. After use, any unused vaccine and all equipment, packaging and materials exposed to the product should be immediately placed in a container for biohazardous materials and disposed off as biohazardous waste.

The recommended schedule of vaccination differs widely among countries.[6] The United States and Netherlands have not used BCG on a national scale. Single dose in infancy is the recommendation of the Expanded Program of Immunization of WHO. In UK, single dose in adolescence was followed, but routine vaccination was withdrawn in 2005 as it was not cost-effective. India introduced BCG in 1948—the first non-European country to do so. Brazil introduced universal BCG immunization in 1967, which continues till date. In Brazil, BCG is repeated in health professionals and people in close contact with patients of TB and leprosy. The recent Brazilian studies confirm that a second dose of BCG does not increase the protective efficacy.[7] BCG is given regularly throughout life in the countries of former USSR. In South Korea, Singapore, Taiwan and Malaysia, BCG is given at birth and again at 12 years. In Singapore, this policy was changed to single dose at birth from 2001, onwards. Repeated vaccination throughout childhood is followed in the Eastern European countries. Depending on Tuberculin negativity or the absence of BCG scar, repeated vaccination is given in Poland. In developing countries with the high incidence of tuberculosis, WHO has recommended the administration of BCG to infants, or as early as possible to children. These policy differences reflect differences in the pattern of tuberculosis among countries, their health services and the differences in opinion about the protective efficacy of BCG.

Postvaccination Reactions

After the administration of BCG vaccination intradermally to an individual who is not infected with tubercle bacilli, the bacilli start to multiply at the site and reach the regional lymph glands through the lymph channels. About two to three weeks after a correct intradermal injection, a papule develops at the site. Within five weeks, the size reaches about 4-8 mm, which then subsides or breaks into a shallow ulcer, usually covered with a crust (Fig. 46.1). Spontaneous healing occurs usually within 6-12 weeks leaving a permanent tiny scar. In the case of subjects naturally infected with tubercle bacilli or with previous BCG vaccination, the local reaction may develop sooner and be exaggerated. This accelerated form is known as Koch's phenomenon. After BCG vaccination, the individual becomes tuberculin positive after a period of eight weeks normally, but may take up to 14 weeks (Figs 46.2A and B).[8]

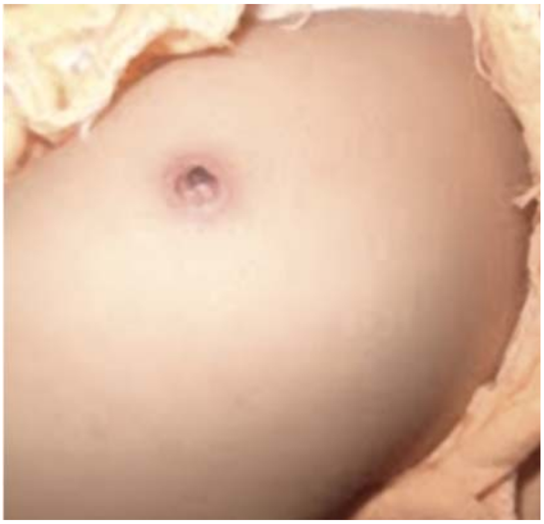

Fig. 46.1: The shallow ulcer–five weeks after BCG vaccination

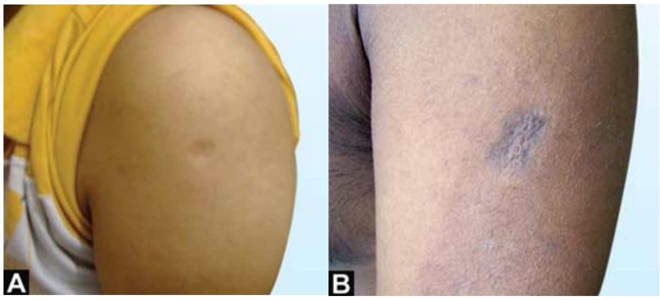

Figs 46.2A and B: (A) Normal BCG scar, (B) BCG scar with keloid

Efficacy of BCG Vaccination

Protective efficacy is a measure of the proportion of people who would have developed the disease, if they had not undergone vaccination. Trials of the vaccine have been undertaken, since it was first developed in 1920s. Despite of this, controversy persists from the very beginning. There are about 20 controlled trials from different countries with highly inconsistent results. Variability in protective efficacy has been observed not only in different trials, but also between the sites of the same trial.[9]

The earlier BMRC trials of 1950s showed that BCG, when given to teenage school-children, gave about 75% protection for 15 years.[10,11] From 1955 to 2005, the national policy in UK was to vaccinate all children aged 12-13 years. As the rates of tuberculosis in teenagers and young adults had declined, the policy was changed since BCG was no longer a cost-effective proposition. The rate of disease in the vaccinated group was so low that about 10,000 vaccinations were needed to prevent one single case, which was relatively easy to treat. Moreover, the adverse effects from the vaccination may outweigh the preventive benefit.[12] This remains the current scenario in many of the developed countries where the rates of tuberculous infection are very low.

Indian Scene

In India, the efficacy of BCG vaccination has been controversial from 1948 onwards since when it was first introduced.

Chingleput Trial

The National Tuberculosis Institute was also concerned with the efficacy of BCG. In 1968, the "Tuberculosis prevention trial"—the largest ever conducted BCG trial was initiated under the auspices of the Indian Council of Medical Research (ICMR), World Health Organization (WHO) and United States Public Health Service (USPHS) with the technical assistance of the National Tuberculosis Institute (NTI). The Chingleput district of Tamil Nadu was selected for the study as this area had a high prevalence of tuberculosis, as well as that of leprosy and this was a vaccination free zone.

Objectives of the Chingleput trial were:

i. To asses the protective effect of BCG vaccination in the noninfected persons.
ii. Effect of BCG vaccination in infected persons.
iii. Protective effect of different strains of BCG.
iv. Epidemiological data on tuberculosis in the community.

The entire population of 3,60,000 persons was registered during the intake and 2,70,000 were administered vaccine and placebo. The study population was divided as three different groups who were given: 1. Madras vaccine; 2. Paris vaccine; 3. Placebo. All the individuals were tuberculin tested; those above 10 years were X-rayed; for those with X-ray shadows: Sputum smear examination and culture were done to detect new cases occurring in the community.

The tuberculosis prevention trial was completed as scheduled. The twelve and a half year report of the trial was rather shocking for the scientific community. It showed that BCG vaccination did not offer significant protection to the adult bacillary type of tuberculosis.[13,14] Some had termed the results as the "great Madras failure" while others called it the "great BCG hoax." Editorials in the newspapers questioned the continued inclusion of BCG in the immunization program. Several expert committees examined all the procedures followed up in the study and came to the conclusion that the study had been meticulously carried out with the best available vaccines.

Even though the study results showed that BCG offered no protection to adult type tuberculosis, the childhood forms of tuberculosis were not studied. A committee of ICMR and WHO studied the epidemiological aspects of the causes of TB in India and concluded that BCG could provide substantial protection against the childhood forms of TB, such as the tubercular meningitis and miliary TB. It is precisely because of the beneficial effects that the continued use of BCG among infants in the immunization program has been recommended.[14]

Two meta-analysis on summary estimates of BCG efficacy have shown a very high rate of protection against meningeal and miliary TB, with the rates being as high as 86% in one clinical trial. It was concluded that BCG offered 51% overall protection and 50% protection against pulmonary tuberculosis.[9,13,14]

Many different theories have been put forward to explain the varying efficacy of the different trials.[6,10]

- Variation in methodology employed in different trials;
- Usage of different strains of vaccine;
- Tuberculin reactivity status of the subjects are different in different trials;
- Mycobacterial strains causing infection may be different in different areas of the world;
- Genetic susceptibility to tuberculosis may vary in between populations;
- Different nutritional states may vary the susceptibility to disease;
- Partial protection by environmental mycobacteria.

Another important issue affecting BCG vaccination is the duration of protection. BCG gives good initial protection, but this may wane off with time.[15] Published data do not provide the evidence of the protective effect of BCG beyond ten years after the vaccination. There is also no evidence to suggest that repeat BCG vaccination or a booster dose increases the protection.[16]

BCG and Leprosy

There is an indirect evidence that BCG vaccine protects against leprosy as well. The range of efficacy varied from 20% in Burma to 80% in Uganda. Even though, there is no significant difference in the pattern of different types of leprosy in BCG vaccinated and non-vaccinated groups, there is reduction in the incidence of reactions, as well as of deformities and disabilities in BCG vaccinated cases. In one of the meta-analysis, protective effect was shown to be 26% in the 7 experimental studies, while the other 19 observational studies had overestimated the protective effect.[17] An additional dose of BCG was more protective in the prevention of leprosy, so a booster dose of BCG is warranted for the contacts of leprosy in areas where leprosy continues to be a public health problem.[8] On the basis of another meta-analysis, which included published data of up to June 2009, there is a strong argument for more emphasis on the role of BCG vaccination in leprosy control and research.[18,19]

Other Uses of BCG

BCG is also used for a number of other conditions, such as for immunotherapy in various forms of cancers. When used in the treatment of superficial forms of bladder cancer, it prevented recurrence in up to 67% of cases. Interstitial cystitis and painful bladder syndrome are treated with intravesical instillation of BCG. It is also used for immunotherapy in colorectal cancer. BCG may protect against the onset of Buruli ulcer. In veterinary medicine, it is used for the treatment of equine sarcoid in horses.

BCG induces the production of TNF-α, which can kill the T-cells responsible for Type-I diabetes. The recurrence of symptoms in patients with multiple sclerosis is reduced with the BCG vaccination.

COMPLICATIONS OF BCG VACCINATION

Adverse reactions to BCG vaccination are rare, provided that correct immunization techniques are used. Vaccination of children with active atopic dermatitis should be deferred until remission since the vaccine may exacerbate the skin condition. Malignancy, corticosteroid treatment, fever, generalized septic skin conditions and immunosuppressive disorders are other relative contraindications. The World Health Organization recommends that people known to be infected with Human Immunodeficiency Virus (HIV) should never be given BCG, but that routine immunization of infants should continue in areas where the incidence of tuberculosis and HIV infection is high.[20] In UK, it is advised that BCG should not be given to infants born to mothers known or suspected to be HIV infected, unless the infants are subsequently confirmed to be HIV negative.[21,22]

There are two major categories of adverse reactions to BCG vaccination: Noninfectious and infectious. Local adverse reactions usually occur at a rate of 0.1 to 0.5 per 1,000 vaccinations. On the other hand, serious, disseminated complications may occur in less than one in one million vaccinations.[23] Most complications (70.8%) are likely to occur at the injection site or in the form of suppurative lymphadenitis. Lesions at the injection site included the formation of ulcers, subcutaneous abscesses, or necrotic lesions due to excessive delayed hypersensitivity reactions. In some reports, abscesses at the injection site occurred more commonly in comparison to lymphadenopathy.[24] Localized or generalized non-fatal persistent BCG infection (10.5%), fatal disseminated BCG infection (0.3%) and post-BCG syndromes, principally keloid scarring (18.2%) are also reported. Keloid scarring is the commonest of the late noninfectious complications. The risk of such scarring is minimized by giving the injection in the skin overlying the lower deltoid area. Injections higher up on the arm are more likely to lead to keloid scarring. Local abscesses and ulcers usually present between one and five months after vaccination, but some may present even later. Lymphadenopathy occurs in the drainage area of the vaccinated site, thus the commonest site is the axilla. Cervical lymph nodes may be affected if the vaccine is given in the upper deltoid region. Most of the BCG complications can be managed with local treatment (Table 46.1).

TABLE 46.1: Various complications of BCG vaccination and their management[21]

Complication	*Management*
Local hypersensitivity reaction	None or topical dressing
Abscess or ulcer at injection site	Drainage or needle aspiration, if indicated. INH or Erythromycin
Regional lymphadenitis	Surgical if there is excessive enlargement, overt suppuration, or sinus formation
Distant lesion, e.g. osteitis	Chemotherapy
Disseminated BCG infection (BCG-osis)	Chemotherapy
Disseminated BCG infection with cardiovascular effects following intravesical instillation of BCG	Chemotherapy with intravenous corticosteroids

Generalized life-threatening hypersensitivity reactions have occurred following the intravesical instillation of BCG. These hypersensitivity reactions are treated with isoniazid (300 mg daily) for three months. BCG therapy is resumed only if benefits exceed the risks.

Extrapulmonary Tuberculosis

Ashok K Janmeja, Prasanta R Mohapatra

INTRODUCTION

Tuberculosis when involves organs other than the lungs, is termed as Extrapulmonary Tuberculosis (EPTB). Around 85% of all types of tuberculosis are of pulmonary type, the remaining 15% are EPTB cases.[1-9] In Human Immunodeficiency Virus (HIV)-infected tuberculosis cases, around 50% have EPTB disease.[10] Based on the Indian data from the Revised National Tuberculosis Control Program (RNTCP) of Government of India, it has been suggested that 18% of all cases of tuberculosis are due to EPTB disease. The proportion of EPTB has shown an upward trend in the recent years both in the developed and the developing countries. In the developed countries like UK and USA, it is mainly due to the immigration of significant number of people from high burden countries, while the increase in the incidence of EPTB in the developing countries of sub-Saharan Africa and South Asia, it is due to HIV coinfection.[3,4,11,12] In the presence of HIV coinfection, lymph node or Central Nervous System Tuberculosis (CNS-TB) are commonly seen.[13]

EPTB cases constitute a bigger chunk in tertiary care hospitals and institutions. Of all the EPTB cases, tuberculosis of the lymph node and the pleura together contribute around 75% of the total number followed by bone and joint tuberculosis, Genitourinary Tuberculosis (GUTB), Tuberculous Meningitis (TBM), abdominal and miliary tuberculosis. Various other organs affected in a decreasing order are: Skin, pericardium, brain parenchyma, larynx, liver, pancreas, eyes, ears, adrenal glands, and pituitary and thyroid gland.

DIAGNOSIS

Diagnosis of EPTB is more difficult than that of pulmonary tuberculosis. Reasons for the same are multifold viz, the difficulties in obtaining the tissue and to isolate mycobacteria from the pathological tissue, uneven distribution of disease, an insidious onset, atypical presentation and limited clinical experience of individual experts from different disciplines. These problems are further compounded by the paucibacillary nature of EPTB, making it imperative to depend on investigations other than on the gold standard for the diagnosis, like the demonstration of Acid-fast Bacilli (AFB) on microscopy. The constitutional clinical features like low-grade evening pyrexia, loss of appetite and weight, malaise and fatigue are also not regular manifestations. Sometimes, the disease may even present with the pyrexia of unknown origin.[14,15] However, clues specific to the involved organ are often helpful to reach to the diagnosis. Nevertheless, physicians must have awareness about various risk factors for EPTB to enable them to have a high index of suspicion for the timely and accurate diagnosis.[16]

In general, EPTB manifestations are nonspecific, not significantly different in the HIV-infected or the non-infected patients, but extensive disease, inadequate or delayed TB treatment and HIV coinfection have been found associated with increased mortality.[17] For the diagnosis of EPTB, all efforts must be exhausted to isolate of tubercle bacilli from the body fluids or the biopsy specimens. Role of Adenosine Deaminase (ADA) estimation in tuberculous fluid collections in various types of EPTB is helpful in reaching the diagnosis. Application of molecular methods, such as Polymerase Chain Reaction (PCR) assay targeting IS6110, multiplex PCR and RT-PCR have been reported useful in the diagnosis of EPTB, particularly where there is strong clinical suspicion, and conventional techniques are not helpful.[18-20]

LYMPH NODE TUBERCULOSIS

Tuberculosis of lymph nodes, caused by both typical *Mycobacterium tuberculosis* and nontuberculous mycobacteria is the most common type of EPTB encountered in the developing world, including in India.[21-23] In USA, nontuberculous mycobacteria are responsible for lymph node disease in children of less than 5 years of age; typical *Mycobacterium tuberculosis* remains the cause of tuberculous lymphadenitis in the higher age group.[24] Lymph node tuberculosis is more commonly seen in the Asians, Hispanics and African-Americans. The disease was historically named as King's Evil and the divine touch of the King was considered as remedy for the illness. Scrofula was another popular Latin name for the entity, meaning glandular swelling. The cervical or supraclavicular nodes are affected in about 70% of the cases, the other sites being the axillary, inguinal or chest wall nodes.[25,26] About 10% cases may have concomitant mediastinal lymph node disease, which occurs due to the retrograde spread from the mediastinum to cervical region.[27,28] Hilar or mediastinal lymph nodes are frequently involved in primary tuberculosis and HIV-infected patients.

Pathogenesis

Lymph node tuberculosis is often a localized manifestation of systemic spread of tuberculous infection. Initially, at the time of primary infection, tubercle bacilli get entry into the lungs and form primary complex. During this stage there occurs hematogenous and lymphatic spread of infection to the rest of the body where bacilli remain dormant. Later, whenever the host defenses get weakened due to local or systemic factors, the dormant foci get reactivated. The systemic nature of the disease is further substantiated by the fact that 1/3rd cervical node tuberculosis cases are associated with current or past pulmonary tuberculosis. Sometimes, in primary lymph node disease, the tubercle bacilli get entry through the tonsils, thereby reaching to cervical nodes resulting in lymphadenitis. Contrary to the lymph node tuberculosis due to typical tubercle bacilli, the atypical mycobacterial lymphadenitis is a highly localized disease. In the atypical mycobacterial lymphadenitis, infection reaches the lymph nodes through tonsils, conjunctiva, gingival or oropharyngeal mucosa, hence, surgical excision is the modality of choice.

The lymph nodes are small, discrete and grow very slowly, but occasionally they grow faster and become tender or painful (Fig. 47.1). Subsequently periadenitis develops, which causes matting and fixation of lymph nodes**.** With the increasing size, there occurs caseation necrosis and liquefaction in the diseased lymph nodes. This leads to the perforation of deep fascia and formation of collar stud abscess. The absence of warmth and redness on the overlying skin earns it a peculiar "cold abscess" name, which is almost synonymous with tuberculous etiology of the abscess. Sometimes, in an immunocompromised host or in HIV infection, the abscess grows very fast making overlying skin warm, erythematous and painful, mimicking an acute pyogenic abscess. Such abscesses may burst and form chronic discharging sinuses or ulcers. The sinuses characteristically have thin, bluish, undermined edges while the discharge is usually watery (Fig. 47.2). The garlanding of neck by multiple lymph nodes, abscesses and discharging sinuses, which used to be a common sight in specialty clinics, is now a thing of past due to an early treatment with effective tuberculosis drug therapy.

Clinical Features

Lymph node tuberculosis is the disease of children and young adults. In the developing countries with high burden of tuberculosis, it is more common in children,

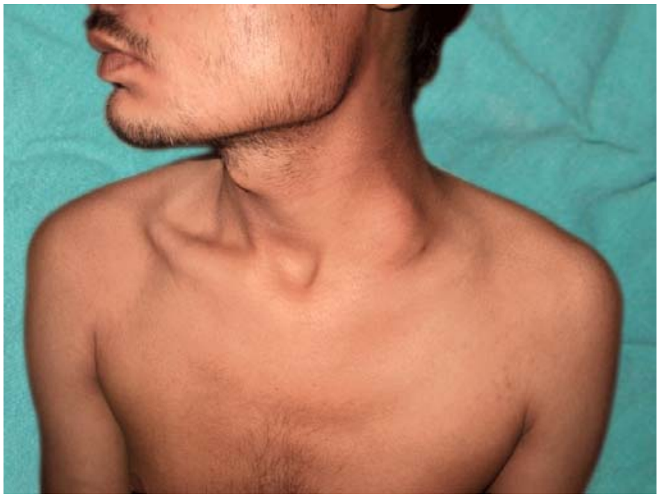

Fig. 47.1: A typical case of tuberculous cervical lymphadenitis

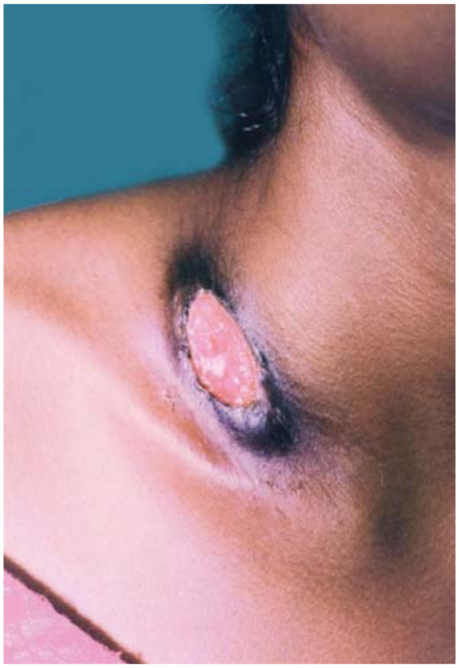

Fig. 47.2: Typical chronic tuberculous ulcer over right cervical region

while in developed countries its peak incidence occurs in age group of 20–40 years. In immunocompetent patients, only a single group of lymph nodes are involved in two-third cases, while multiple groups are affected in remaining one-third cases, around 90% of HIV-infected cases have involvement of multiple groups of nodes. Also, concomitant intrathoracic or intra-abdominal lymph node involvement and pulmonary tuberculosis are common in HIV-infected cases.[22,29-31] Apart from the main symptom of the local visible swelling, enlarged nodes may result in other signs and symptoms due to obstruction or pressure on adjacent viscera, e.g. mediastinal lymphadenopathy can cause dysphagia, tracheoesophageal or esophagomediastinal fistula. Chylothorax, chyluria or chylous ascites may develop as a result of pressure on thoracic duct due to upper abdominal or mediastinal lymphadenopathy. Although rare, obstructive jaundice has also been reported due to the obstruction of biliary duct by enlarged lymph nodes at porta hepatis.[32]

Diagnosis

It usually presents as slowly enlarging swelling in cervical region in children without causing much pain or discomfort. Concomitant mediastinal and hilar nodal enlargement is seen in around 5 to 12% cases. The incidence of concomitant pulmonary tuberculosis is highly variable. Ultrasonography (USG), Computed Tomography (CT) scanning and Magnetic Resonance Imaging (MRI) help to demarcate the extent of disease, whenever nodal involvement in mediastinum and abdomen is suspected. Enlarged nodes with hypodense areas, calcification, peripheral rim enhancement and central necrosis are the common imaging findings (Fig. 47.3). The gold standard for diagnosis of tuberculous lymphadenitis is the excision biopsy. Demonstration of AFBs in Fine Needle Aspiration Cytology (FNAC), pus or biopsy specimens from the affected glands constitute the most authentic diagnosis. Although, AFB positivity rate is not very impressive, larger biopsy sample may show positivity rate up to 50 to 70%.[32-36] Infrequent demonstration of bacilli on direct smear examination is due to the paucibacillary nature of the disease. In selected cases, endoscopic ultrasound-guided FNAC can be used for assessing mediastinal and abdominal lymphadenopathy. The modality is a safe, minimally invasive and accurate outpatient diagnostic technique in suspected EPTB cases.[37]

Treatment

Antituberculosis drug therapy alone is quite adequate to achieve cure in the majority of cases caused by typical tubercle bacilli. The recommended treatment for

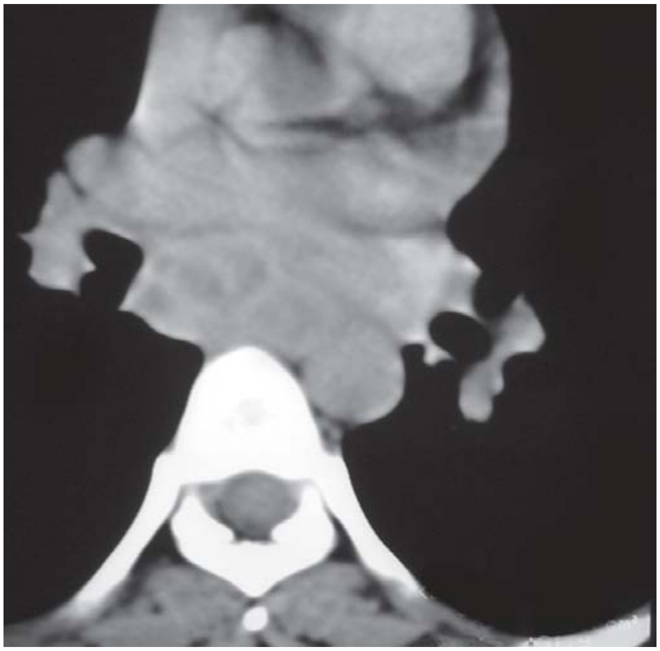

Fig. 47.3: CT imaging showing enlarged mediastinal lymph nodes with hypodense areas, peripheral rim enhancement and central necrosis

previously untreated lymph node tuberculosis consists of short-course chemotherapy regimens of six months duration, in which four drugs, i.e. isoniazid (H), rifampicin (R), pyrazinamide (Z) and ethambutol (E) are given for the initial two months in the intensive phase followed by two drugs (HR) for four months in the continuation phase. The Revised National Tuberculosis Control Programme (RNTCP) of the Government of India, and several other Similar National Control Programs elsewhere follow the WHO recommended Directly Observed Therapy Short Course (DOTS) strategy under which drugs are administered intermittently thrice a week. Under RNTCP, the lymph node tuberculosis has been considered a milder and paucibacillary form of tuberculosis, hence, has been placed in category III treatment regimen. Recent studies have demonstrated that the DOTS strategy is an effective treatment modality with treatment completion and success rate of 95 to 97%.[38,39]

While treating lymph node tuberculosis, a paradoxical phenomenon is encountered during the ongoing drug therapy in some cases. There occurs the enlargement of existing nodes or even new lymph nodes may appear ipsilaterally or contralaterally in the same group of nodes, or otherwise. Biopsy samples or aspirate of these nodes do not grow TB bacilli, the phenomenon does not represent the relapse or treatment failure. These lymph nodes tend to regress spontaneously on the continuation of the same drug regimens without any alteration. There is no need of changing the drug regimen in such situations. This phenomenon is mostly attributed to hypersensitivity to tuberculoproteins released due to the bactericidal action of drugs or the disrupted macrophages. The phenomenon of paradoxical response to tuberculous chemotherapy is also termed as Immune Reconstitution Inflammatory Syndrome (IRIS). Sometimes, the response is highly exaggerated when lymph nodes get significantly enlarged, become painful or lead to abscess formation. When located in the mediastinum, such enlarged nodes tend to mechanically press the esophagus or tracheobronchial tree, thereby causing dysphagia or respiratory difficulty respectively (Fig. 47.4). In such situations, addition of a short course of corticosteroid is recommended, after the exclusion of other usual causes of treatment failure.[40]

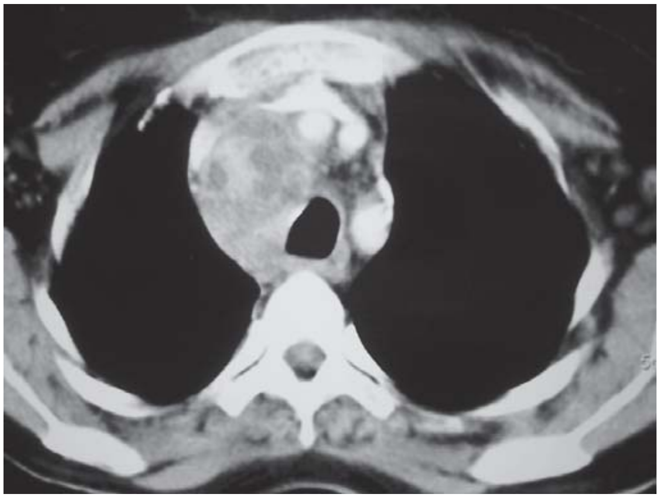

Fig. 47.4: CT image showing enlarged mediastinal lymph node compressing tracheobronchial tree

PLEURAL EFFUSION

Tuberculous pleural effusion is the second most common type of EPTB. Nearly 20% of all EPTB cases in both HIV-infected and non-infected patients have pleural effusion. Also, tuberculous pleural effusion is the most common cause of lymphocytic exudative type of effusions in high tuberculosis burden countries like India. Although the fluid collection is intrathoracic in the pleural cavity intimately covering the lung, the entity is generally classified as extrapulmonary disease.[35,41-44] (See details in the chapter on TB Pleural Effusion).

Tuberculous Empyema Thoracis

Tuberculous empyema represents a chronic, active infection of the pleural space resulting into the collection of frank pus loaded with large number of tubercle bacilli. The condition is uncommon than tuberculous pleural effusion.[45] Tuberculous empyema commonly develops as a sequel to thoracoplasty, artificial pneumothorax or inadequately treated pleural effusion. The onset is usually gradual with the symptoms of mild fever, fatigue, weight loss, chest pain, dyspnea and cough. Skiagram chest shows pleural effusion, but often with the thickening of pleura, pleural calcification, loculation or encystment. Finger clubbing, intercostal narrowing with tenderness or empyema necessitatis may be seen on examination. Treatment consists of pleural pus drainage and antituberculosis chemotherapy. Problematic treatment issues include the inability to reexpand the trapped lung and difficulty in achieving therapeutic drug levels in pleural fluid, which can lead to drug resistance. The treatment may require decortication or thoracoplasty, should an adequate tuberculosis drug therapy coupled with repeated pleural tappings fails. Surgery should be undertaken by experienced thoracic surgeons.[45]

BONE AND JOINT TUBERCULOSIS

Spinal Tuberculosis (Pott's Disease)

It is the most common type of osseous tuberculosis, nearly half of the bone and joint cases are due to spinal involvement, other site being the hip joint. Usually, weight-bearing joints are affected by tuberculosis.

Pathogenesis and Clinical Features

Usual constitutional symptoms may be seen well before the localizing signs become actually perceivable. Often, local signs at the involved site or at the site of extended disease are more prominent. In spinal tuberculosis, lower thoracic and upper lumbar vertebrae are commonly affected, followed by middle thoracic and cervical region vertebrae. Usually, more than one adjacent vertebra is involved and the body of the vertebrae is preferentially affected rather than its other elements. The tubercle bacilli reach skeletal tissue as a result of hematogenous spread during primary tuberculous infection. The disease originates in the cancellous area of bone close to the superior or the inferior end-plates and extends into intervertebral disc after penetrating the subchondral bone plate and thence to the body of adjacent vertebra. With further progression, there occurs the demineralization of end plates and softening of body leading to vertebral collapse or anterior wedging (Fig. 47.5). This is responsible for typical angulation or gibbus deformity in the spine seen in Pott's disease patients. The spread of disease may also follow sub-anterior longitudinal ligament route. The subligamentous spread of tuberculous abscess downward away from the primary involved vertebra can cause the destruction of anterior surface of other vertebral bodies.

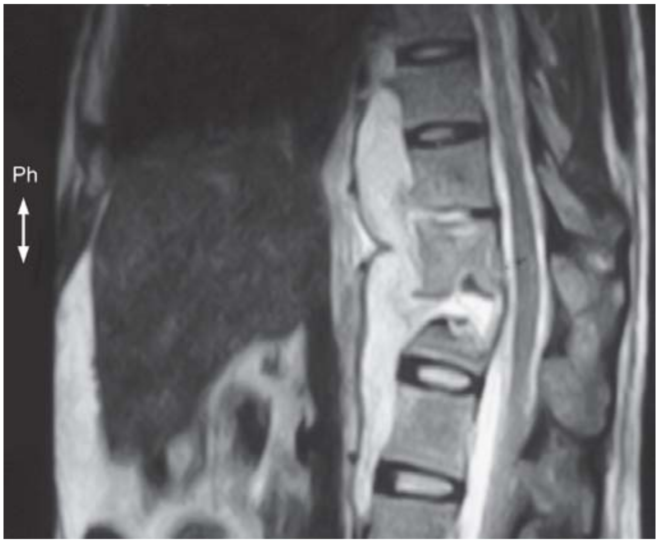

Fig. 47.5: MRI image of young male suggests partial collapse of D12 vertebra with the involvement of intervening disks and prevertebral abscess suggesting spinal tuberculosis

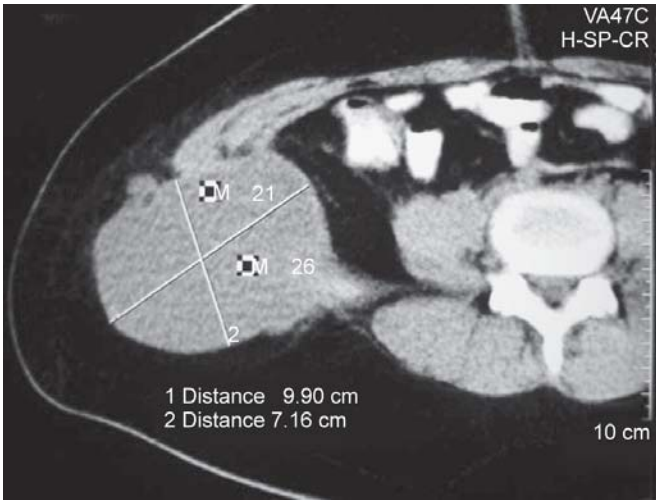

Fig. 47.6: CT scan pelvis reveals abscess in the right iliac fossa. There was pus collection both medial and lateral to right iliac bone. About 300 ml of pus was aspirated under ultrasound guidance and the pus was found positive for tubercle bacilli

These exudates tend to spread following the path of least resistance along with fascial planes, vasculature and nerves, and present as cold abscesses elsewhere. Commonly, such an abscess is seen as a paravertebral abscess, psoas abscess in lumbar region, or abscess in iliac fossa (Fig. 47.6), some even gravitate below the inguinal ligament on medial side of thigh. Sometimes, it spreads laterally from the iliac fossa to appear over the iliac crest. Rarely, it tracks with gluteal or femoral vessels to form gluteal or Scarpa's triangle abscess.[46] If the cervical spine is involved with tuberculosis, the exudates track down in prevertebral area as a retropharyngeal abscess, which may mechanically cause deglutition and respiratory difficulty or hoarseness of voice. Accumulation of pus in the mediastinum may present as posterior mediastinal mass from where it can spread to the pleural cavity, esophagus or trachea.

Paraplegia (Pott's paraplegia) develops in about 30% cases of Pott's disease.[46,47] Commonly, it is the mechanical pressure on the cord, sometimes nonmechanical causes are responsible for such neurological complications. Generally, paraplegia develops during the course of active disease, but rarely it may occur years after cure, even without any TB reactivation, possibly due to the formation of a ridge of bone anterior to cord, fibrosis of dura mater or gliosis of cord.

Diagnosis

Plain radiography reveals narrowing or disappearance of disk space, area of destruction in the body and wedging or collapse of the vertebral bodies. The bony changes become perceivable on plain radiograph only about five to six months after the onset of pathology. However, CT and MRI scans may pick up such lesions quite early, also, the extent of associated complications is demarcated better with these investigations. The CT and MR imaging are particularly useful to study the status of the spinal cord or the canal and to pick up the involvement of posterior elements of vertebrae. Some of the complications, such as the prevertebral abscess in neck region and the typical fusiform abscess in the dorsal spine area, can also be appreciated better with such imaging. Healed psoas abscess may show calcification too. Often, typical clinicoradiological or MRI is quite adequate to diagnose spinal tuberculosis. However, in atypical presentation, differentiation is required from conditions like pyogenic osteomyelitis, mycotic infection, syphilis, neoplasia, multiple myeloma, lymphoma, chondroma, metastasis, traumatic fracture or sarcoidosis, and others. In such situations, biopsy of the affected vertebrae and culture of the contents would be necessary to clinch the diagnosis.

Tuberculous Arthritis

Tuberculous arthritis is typically a monoarticular disease, although multiple joint involvement has been described in literature.[46,48] About 15% of all skeletal tuberculosis cases are constituted by hip joint and about 10% cases by knee joint TB, shoulder joint is rarely involved. Involvement of joint may occur as a result of direct extension from adjacent tuberculous osteomyelitis or through hematogenous spread during primary tuberculosis. Clinicopathological staging of joint tuberculosis usually decides the clinical features for that stage. Pain and circumferential limitation of joint movements are typical clinical features. Osteolytic areas and tuberculous sequestra are encountered along with the loss of the definition of articular margins. In advanced stages, periarticular osteoporosis, peripheral bony erosions and gradual reduction in joint space constitute a radiological triad suggestive of joint tuberculosis. Pyogenic, fungal and rheumatoid arthritis may need differentiation from joint tuberculosis.

Poncet's Disease

This is defined as parainfective polyarthritis in which active tuberculosis is located anywhere in the body, not necessarily in the affected joints, AFBs are never isolated from the involved joints. Commonly, the extra-articular site of active tuberculous disease is the lymph node.[48-50] This is basically a tuberculous hypersensitivity phenomenon, commonly accompanied by strongly positive tuberculin skin test or erythema nodosum. Mostly seen in children or young adults, it commonly involves knee, ankle, wrist, elbow, metacarpophalangeal and proximal interphalangeal joints. Constitutional features, including fever, pain, swelling and tenderness of the involved joints are generally present. Synovial fluid is exudative type, but fluid is sterile, negative for AFB and even PCR is negative for mycobacterium. The condition responds very well to the drug treatment of basic active tuberculous disease.

Tuberculosis Osteomyelitis

Osteomyelitis is usually seen in the bones of extremities involving small bones of hands and feet, like phalanges, metacarpals and metatarsals. Although tuberculosis can involve any bone, the long bone disease is rare. The disease commonly presents with clinical features, such as pain, swelling with raised temperature, tenderness and boggy soft tissue at the involved site. An abscess or sinus may also be encountered. The condition needs differentiation from chronic pyogenic osteomyelitis and neoplasia. The typical radiographic picture reveals honey combing, sequestration of diaphysis and subperiosteal new bone formation.

Treatment of bone and joint tuberculosis: Overall consensus is that spinal tuberculosis without neurological involvement and without unsightly deformity is a medical condition. Combined management, the modality of choice consists of orthopedic intervention by surgeon and tuberculosis drug therapy under supervision of physician. The basic principles of tuberculosis drug therapy regimens essentially remain the same as for pulmonary tuberculosis. There have been some difference of opinion regarding the duration of therapy, the orthopedicians favored a larger 18–24 months duration of drug therapy in the past.[51,52] However, the latest evidence suggests that short course chemotherapy of nine months duration is quite adequate.[53,54] It is also recommended that six-month short-course regimen with four drugs (HRZE) in the intensive two months phase and two drugs in the subsequent four months maintenance phase is sufficient for the cure.[54] Latest WHO guidelines have also endorsed that pulmonary and EPTB should be treated with same regimens, but because there are technical difficulties in the assessment of treatment response of bone and joint tuberculosis, the nine-month treatment is recommended for such cases.[55]

CENTRAL NERVOUS SYSTEM TUBERCULOSIS

Only about 5% of all extrapulmonary tuberculosis cases are contributed by CNS-TB, but the CNS-tuberculosis has a high morbidity and mortality. In developing country like India, the prognosis of disease had been poor due to inadequate availability of diagnostic and treatment facilities. Human immunodeficiency virus has compounded the risk for the development of CNS-TB. In one study its occurrence was found in up to 2 cases of 100 HIV-infected persons.[13]

Pathogenesis

Tubercle bacilli reach the brain parenchyma and the meninges during the stage of hematogenous spread of primary complex formation. Thereupon, these bacilli form tiny lesions during primary complex stage prior to the development of delayed hypersensitivity or cell-mediated immunity. In more than 95% cases, these lesions get healed by natural healing with the appearance of cell mediated immunity. Later in life, such lesions may get reactivated and present with different clinical variants of CNS-TB (Table 47.1).

TABLE 47.1: Different clinical forms of CNS tuberculosis

- Meningitis (TBM)
- Tuberculoma
- Arachnoiditis
- Encephalitis
- Arteritis or vasculitis
- Tuberculous abscess
- Radiculomyelitis
- Behavioral abnormalities
- Demyelination

Once reactivated, the foci may rupture into the subarachnoid space leading to arachnoiditis or grow intracranially as tuberculomas. Frequently, CNS-TB is the part of disseminated tuberculosis, about 20% of such patients have concomitant miliary tuberculosis. Occasionally, direct extension from tuberculosis of contiguous parts would lead to CNS-TB, like from skull bone disease, tuberculous otitis or spondylitis. Rarely, extradural tuberculous abscess may occur with vault tuberculosis.[56] When tubercle bacilli enter the Cerebrospinal Fluid (CSF), there occurs intense inflammation of meninges, i.e. tuberculous meningitis, the meninges get covered with thick gelatinous grey exudates. The latter get extended to brainstem affecting the cranial nerves. Exudates further track down the spinal cord and spinal roots of the nerves. The thick gelatinous material also interferes with CSF drainage system, thereby causing hydrocephalus, quite frequently.

Clinical Features

The TBM usually develops as a complication of primary tuberculosis, hence commonly seen in early childhood, but may occur at any age. The initial symptoms of disease are nonspecific in the form of loss of appetite, irritability, malaise, vomiting, headache, changed behavior, drowsiness or even convulsions. These features usually mark the prodromal stage of the disease, which may last for two to eight weeks. Neck retraction or rigidity may be accompanied at this stage due to meningeal inflammation. In infants, fontanelle may be bulging. Around 50% cases have papilledema, but usually without the loss of vision. Increasing hydrocephalus is responsible for decreasing consciousness and brain damage. Choroid tubercles may also be seen in some cases. Tuberculous meningitis patient can be classified in different clinical stages depending upon the level of consciousness and presence of neurological deficits.[57]

Diagnosis

TBM often needs to be differentiated from other types of meningitis like bacterial, fungal, viral, carcinomatous or neurosyphilitic. The diagnosis is easy in the presence of suggestive clinical features and associated pulmonary or miliary tuberculosis, the conditions seen in more than half of such cases. In HIV infected persons, the concomitant EPTB is more common. Suggestive features on CT and MRI scan, such as hydrocephalus, tuberculomas, gyral enhancement, infarcts and basal exudates, also help in making the diagnosis. MRI images are particularly useful in differentiating tuberculosis from fungal, viral and bacterial disease.

CSF findings play a vital role in the diagnosis of CNS-TB. Although CSF pressure is found elevated and papilledema is present, lumbar puncture can be performed safely because it is a chronic type of meningitis. White cell counts are raised with polymorph predominance initially, but lymphocytes take over in later stages. The counts are not elevated more than 500/cmm. Usually, CSF is clear and its glucose level is less than 40% of the corresponding blood glucose level. Proteins in CSF are in the range of 100–200 mg/dl usually, may exceed 1 gm/dl in the event of spinal block due to coexisting spinal meningitis. If allowed to stand, one can see the cobweb formation in CSF. Chloride estimation in CSF is not helpful in differentiating TBM from viral or bacterial etiology. In about 5% TBM cases, CSF may be normal. In the presence of HIV infection, CSF remains unremarkable and not helpful in making diagnosis. Nevertheless, CSF must be sent in HIV-infected patients for AFB culture, it may come out to be positive in up to 50% cases. Sterile CSF culture for bacteria, fungi and negative Gram staining are supportive of TBM diagnosis. A cut off level of more than 10U/L, CSF-ADA has sensitivity of 92.5% and specificity of 97% for the diagnosis of TBM.[58] Values more than 8U/l (sensitivity <59% and specificity >96%) improved the diagnosis of TBM ($p < 0.001$).[59] PCR test for *M. tuberculosis* among Indian patients had sensitivity of 44.5% and specificity 92% in the most likely TBM cases.[58]

CT scan and MRI imaging often demonstrate findings in CNS-TB, such as thickening and enhancement of basal meninges, small granulomas, infarction and hydrocephalus, periventricular edema, tuberculous abscess and tuberculoma (Fig. 47.7). These are quite helpful in reaching the diagnosis as well as for following the progress of treatment. Serial CT scans performed for assessing the course may sometimes reveal new tuberculomas or accentuation of those pre-existing during tuberculosis drug therapy, the phenomenon recognized as paradoxical response.[60,61] However, such accentuated lesions get resolved gradually with the continuation of the same chemotherapy. A substantial series has recently described the radiological features of paradoxical neurological TB-IRIS in HIV-infected patients with tuberculoma.[62]

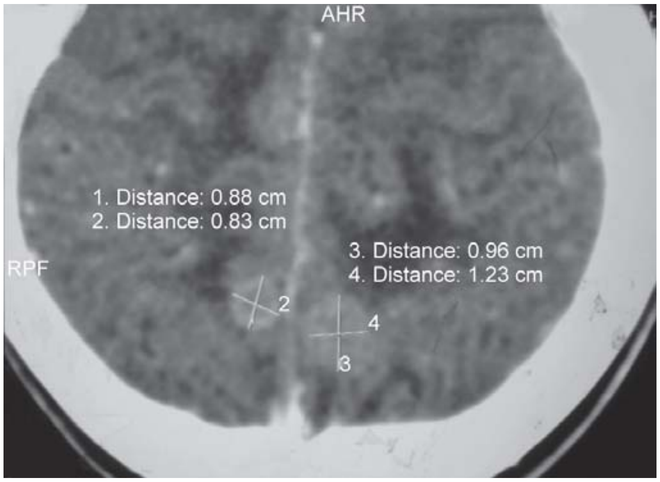

Fig. 47.7: CECT head showing hypodense lesions with rim shadow in a typical case of tuberculoma

Treatment

Tuberculous meningitis is a serious form of tuberculosis in the terms of morbidity and mortality, hence a better prognosis can only be anticipated if the disease is detected at an early stage and right treatment is initiated without wasting any time. Isoniazid, pyrazinamide and ethionamide penetrate the Blood Brain Barrier (BBB) adequately; rifampicin enters poorly while streptomycin and ethambutol cross BBB adequately only when meninges are inflamed. Four drugs [HRZS/E] should be included in the intensive phase. Ethambutol is avoided in comatose patients because vision cannot be monitored. Therefore, streptomycin should be substituted for ethambutol accordingly. Intrathecal streptomycin is no longer used. The optimum duration of TB drug therapy is still debatable. Even in the absence of randomized controlled trials to compare the efficacy of 6 months verses 12 months regimens, the meta-analysis of available literature suggests that six-month regimens are as affective as longer duration regimens provided the bacteria are fully susceptible to first line drugs.[63] However, chemotherapy for 9–12 months of treatment is recommended for TBM, because of the serious risk of mortality and morbidity.[63,64]

The use of corticosteroids is somewhat controversial. Although its use does not benefit stage I, but it improves prognosis in stage II and III disease. Therefore, if nothing is suggestive of drug resistance and fungal etiology is ruled out, corticosteroid should be used as adjuvant to tuberculosis drug therapy in stage II and III TBM.[64] A recent Cochrane review supports the routine use of corticosteroids in HIV-negative patients with TBM to reduce mortality and disabling residual neurological deficits, however, not adequate evidence is yet available in favor or against a similar conclusion for those who are HIV positive.[65] Surgery is sometimes necessary for the management of hydrocephalus, an early drainage improves the outcome.[66] Surgical drainage of intracranial or extradural abscess will also be necessary.[67] Tuberculomas usually regress with chemotherapy; therefore, a trial of at least two months drug therapy must be given before surgery.

ABDOMINAL TUBERCULOSIS

Abdominal tuberculosis, which encompasses tuberculosis of Gastrointestinal Tract (GIT) anywhere from esophagus to anus, peritoneum, mesentery, omentum, mesenteric lymph nodes, hepatobiliary system, spleen and of pancreas, accounts for 3% of all EPTB cases, concomitant pulmonary lesions are found in about 25% of such cases. The incidence is expected to increase with an increase in the HIV incidence, EPTB is more commonly encountered in HIV-infected cases. A pre-chemotherapy era autopsy series of pulmonary TB cases had revealed intestinal involvement in 55 to 90% cases, the disease was more common in the presence of extensive pulmonary involvement.

Pathogenesis

The tuberculosis infection reaches the abdominal organs through hematogenous spread during primary infection stage, from swallowing of sputum loaded with tubercle bacilli in pulmonary tuberculosis patients, through direct extension from adjacent organ tuberculosis and occasionally through lymphatics. Intake of milk infected with *Mycobacterium bovis* causing tuberculosis is not common these days due to the universal practice of pasteurization or boiling of milk before consumption. The intestinal disease in India is primarily caused by *M. tuberculosis* and not by *Mycobacterium bovis*.[68] The most common site for abdominal TB is the ileocecal region possibly due to the abundance of lymphoid tissue in the Peyer's patches, physiological stasis and minimal digestive work undertaken in this part of intestine allowing more contact time to bacilli for invasion. The disease spreading from lymph nodes, intestine or from fallopian tubes usually leads to peritoneal tuberculosis. In about 30% cases, lymph node and peritoneal tuberculosis may be seen even without the intestinal disease.[69]

When the bacilli reach the intestine, they are trapped in the Peyer's patches, consequently granuloma formation takes place therein. These granulomas grow and get confluent with each other. The inflammation spreads to the submucosa, and the mucosa overlying the inflamed Peyer's patches ulcerate. These ulcers are superficial, do not penetrate beyond muscularis propria.[70] The ulcers are transversely placed covering a ring of the intestinal mucosa and so, appropriately named as girdle ulcers. The ulcers may be single or multiple, the mucosa in between the girdle ulcers is quite healthy, termed as skip lesion. Stricture formation ensues when these ulcers heal by fibrosis. The strictures called "napkin ring strictures", are often responsible for intestinal obstruction. Other areas in intestine may show no granuloma formation, but for chronic inflammation. Sometimes, there occurs excessive inflammation and fibrosis causing adhesions of gut, mesentery and lymph nodes assuming altogether a shape of a mass, which may erroneously appear as neoplasm.

Grossly, intestinal tuberculosis is classified as ulcerative, ulcero-hyperplastic and hyperplastic. While ulcerative and hyperplastic forms (stricture form) are seen in small intestine, ulcero-hyperplastic form is found in colon and ileocecal region. Tuberculous peritonitis occurs in different forms: Ascetic, encysted and fibrinous, sometimes felt as an abdominal mass comprising of a mesentery and thickened omentum. Gross examination on laparotomy/laparoscopy exhibits straw colored fluid, multiple yellow-white tubercles scattered over peritoneum or greater omentum; the peritoneum lacks its usual shine and hyperemia.[71] The involved abdominal lymph nodes may be enlarged and matted with or without caseation. Granulomas are commonly seen in the lymph nodes.

Clinical Features

Clinical presentation of abdominal tuberculosis is quite protean, may mimic many acute or chronic intestinal ailments. Nearly two-third cases of abdominal tuberculosis are young adults of 20 to 40 years of age with slight preponderance for female gender. The onset of symptoms may be acute, chronic or acute on chronic. Often, about one-third present as acute abdomen with pain in right iliac fossa mimicking acute appendicitis or as acute intestinal obstruction, while the remaining two-third have insidious onset with symptoms like pain in abdomen. Constitutional symptoms of low grade fever, malaise, anorexia and weight loss are often present. Pain in abdomen is seen in around 80 to 95% cases, while alternate constipation and diarrhea are seen in about 9 to 20% cases. Other features like a moving ball of wind in abdomen, nausea, vomiting and malena may also be seen. Features of malabsorption are also encountered in some cases. No characteristic signs are described for abdominal tuberculosis, the popular classical "doughy" feel of the abdomen has been observed in 6 to 11% cases in Indian series, however, not reported in some large series.[72] Right iliac tenderness like that in acute appendicitis or lump in this region mimicking carcinoma or appendicular abscess may be felt. The signs of acute or subacute small intestinal obstruction like abdominal distension, vomiting and absolute constipation with or without a palpable mass may be encountered as per the pathological stage of the disease. Many other clinical features ensue depending upon the involved organ or the site and type of involvement.

Diagnosis

Clinical presentation of abdominal tuberculosis is quite nonspecific and usually overlapping with malignant or inflammatory bowel diseases. Nevertheless, a high index of suspicion particularly arises for persons hailing from high burden countries with suggestive constitutional symptoms and evidence of pulmonary or EPTB lesions. Anemia, reduced serum albumin (<3.5 gm/dl) or raised C-reactive proteins and positive tuberculin skin test are usually present, but not deciding investigations. Thus, the only disease site specific clinical features, radiological and Ultrasonography (USG) findings, pathological lesions (both gross plus microscopic) and isolation of mycobacteria, altogether are necessary for clinching the authentic diagnosis in the majority of cases. The following radio imaging techniques are substantially helpful in arriving at the diagnosis of abdominal tuberculosis:

1. *Chest radiograph:* Concomitant pulmonary lesions either healed or active, have been reported in 25 to 80% of abdominal tuberculosis cases.[70,73,74] There may be features suggestive of pulmonary TB, pleural effusion or mediastinal lymphadenopathy. In such situation, effort should be made to demonstrate tubercle bacilli in sputum, Bronchoalveolar Lavage (BAL) or gastric lavage in children. The presence of tuberculous lesion elsewhere in the body supports the diagnosis of abdominal tuberculosis.
2. *Plain abdominal radiograph:* The presence of certain findings, such as multiple air fluid levels with distended bowel loops (intestinal obstruction), ascites, perforation or intussusception and calcified nodes indirectly support the diagnosis.
3. *Small bowel barium study:* Hypersegmentation of barium column also called as chicken intestine, stiffened and thickened folds, luminal stenosis with smooth and stiff contours (hour glass stenosis), and multiple strictures with the segmental dilatation of intestinal loops are various suggestive signs. Similar findings may be encountered in Crohn's disease.
4. *Barium enema:* The thickened ileocecal valve gives a broad triangular picture having base towards cecum, popularly known as "inverted umbrella" sign. Extreme irritability due to ulceration causes the rapid movement of barium, hence no barium contrast is visualized in inflamed segments of the ileum, cecum and ascending colon with normal column of barium on other side, also described as "Stierlin's sign". Whenever there is stenosis in the gut, a very narrow string of the contrast is visualized, known as "string sign". Both Stierlin's and String's signs may also be positive in Crohn's disease, hence are not specific for tuberculosis.
5. *Ultrasonography:* Ultrasound is helpful in picking up the ascites (either loculated or free), thickened omentum, retroperitoneal or mesenteric lymphadenopathy. Ultrasonographic guidance for investigations like FNAC or fluid tapping always adds to the diagnostic yield.
6. *CT scan:* There occurs circumferential thickening of the wall of cecum and terminal ileum. Also, the ulceration and nodularity in terminal ileum along with narrowing and proximal dilatation may be visualized. Other abnormalities like obstruction, perforation and abscess can also be seen on CT scan. In tuberculous ascites, fluid density is usually very high, i.e. around 25–45 HU due to high protein content of the fluid. Peritoneal thickening and nodules may also be seen.

To confirm the diagnosis, we need to demonstrate AFB in peritoneal fluid or typical histopathological picture in the biopsy taken through laparotomy. Blind percutaneous needle biopsy of peritoneum can also be performed. However, biopsy under direct visualization is always safer as it averts complication like gut perforation and gives a high diagnostic yield. Laparoscopy is the procedure of choice for biopsy, but mini laparotomy would be preferable in the presence of intense plastic peritonitis and extensive adhesions. Colonoscopic FNAC may be taken from the ileocecal lesions to improve its yield. Ascitic fluid is straw-colored exudative type with total cell count of around 150–4000/cmm, lymphocytes being more than 50%. Ascitic fluid AFB positivity rate is usually less than 20%. The culture positivity could be improved up to 83%, when at least 1 liter fluid was centrifuged and subjected to culture for tubercle bacilli.[75] Ascitic fluid ADA level of more than 40 U/L is highly supportive of tuberculous etiology. High level of interferon-gamma in ascitic fluid is also suggestive of tuberculous etiology. The role of immunological investigations for diagnosis of tuberculosis is still undefined.

Treatment

The treatment is essentially same as for pulmonary tuberculosis. All patients of abdominal tuberculosis should be treated with short course chemotherapy for six months duration. The standard regimen includes four drugs (HRZE) in the initial two-month intensive phase followed by two drugs (HR) in the four-month continuation phase. Six months short-course chemotherapy compared with 12 months chemotherapy regimen, achieved cure in 99% cases.[76] Six-month regimen is the standard regimen for the treatment of abdominal tuberculosis as per the recommendation of the Joint Tuberculosis Committee of the British Thoracic Society.[54] The routine use of adjuvant corticosteroid is not advisable in such cases.[72]

Surgery in the form of intestinal resection and end-to-end anastomosis, is occasionally required, only if there is mechanical obstruction.[72,77,78] It is particularly indicated for strictures of longer than 12 cm with involvement at multiple sites. Obstructive intestinal lesions may respond to chemotherapy alone, without surgery. In one report, 91% patients had clinical improvement and 70% had complete radiological resolution while only 8% required surgery at the completion of chemotherapy.[79] Sometimes, the obstructive symptoms may increase initially, but only to regress ultimately. On an average, it takes around six months for the amelioration of obstructive symptoms.

GENITOURINARY TUBERCULOSIS

Genitourinary tuberculosis is a significant problem in the developing world, around 9% of all EPTB cases in India are estimated as of GUTB.[10] Often, the disease continues to progress since the diagnosis is not made until it is too late.[14] Most patients present with renal failure, bladder and or ureteric strictures, which could have been easily averted, had an early diagnosis and treatment made available to them. Three to four percent cases of pulmonary TB also have concomitant GUTB, commonly involving the kidneys, bladder, urethra, and male or female genital tract.[1,10]

Pathogenesis and Clinical Features of Urological TB

The mycobacterial infection reaches the kidneys and other urogenital organs during the stage of hematogenous spread of primary tuberculosis. These bacilli form tiny lesions as tubercles in these organs, which heal either spontaneously or with treatment, only to get activated after the years of dormancy. The disease usually occurs during the second and fourth decade of life. The most common clinical presentation of urological tuberculosis is sterile pyuria and painless hematuria. Patient may present with the symptoms of dysuria, hematuria, frank pyuria and renal mass. The features are quite suggestive of recurrent urinary tract infections with fever, but for any isolation of common bacterial growth on culture. The granulomas formed in the kidneys enlarge and rupture leading onto bacilluria. The infection spreads downward to the calyces, pelvis, ureter and bladder. Ureteric stenosis may develop particularly in the distal region giving rise to obstructive uropathy, which may result in tuberculous pyonephrosis. The bladder involvement causes features of cystitis and bladder wall fibrosis. The latter results in the marked reduction of bladder capacity, commonly termed as thimble bladder deformity. The reduced bladder capacity is responsible for the frequency of micturition and nocturia.

Pathogenesis and Clinical Features of Gynecological TB

Infertility, either primary or secondary is a common presentation in female genital tuberculosis. In India, one-third cases of tubal disease infertility are attributed to tuberculosis.[80] Alterations in menstrual pattern (menorrhagia, amenorrhea or postmenopausal bleeding) are common features in such patients. Female genital tuberculosis may be mistaken for ovarian malignancy. The differentiation is further complicated by the presence of high levels of CA-125, which are also described in gynecological tuberculosis. Primary female genital tuberculosis is rare, usually seen when the male partner suffers from active genitourinary tuberculosis.[81,82] Mostly, genital TB is almost always secondary to tuberculosis elsewhere in the body. Commonly the infection spread directly from active abdominal tuberculous pathology.

Diagnosis

Sterile pyuria should raise the suspicion of GUTB. Urine culture for mycobacteria, particularly the collected early morning samples of three consecutive days give better yield. The intravenous pyelography is an important investigation for the diagnosis of urological tuberculosis. The pyelogram may reveal abnormalities, such as the calyceal clubbing and pelviureteric junction stenosis with pelvic dilatation. Calcification in urinary tract and prostate may support the diagnosis of tuberculosis. Hydronephrosis, and sometime small kidney may be seen on ultrasonography. Urinary tract and kidney abnormalities can also be picked on CT scanning. Sometimes, perinephric or psoas abscess may also be encountered. In males, the involvement of vas deferens will give a beaded feel on palpation and a draining scrotal sinus can also be seen. Diagnosis is confirmed by growing AFB from urine or biopsy tissue culture. Urine for tubercle bacilli is usually not rewarding. Moreover, the positive microscopy may also raise the suspicion of contamination either by *Mycobacterium smegmatis*, a saprophytic mycobacteria or of environmental mycobacteria in laboratory reagents. Diagnosis of female genital tuberculosis is made with the help of multiple criteria, including the menstrual blood culture. FNAC, endometrial curettage and laparoscopic biopsy as per an algorithm defined for use in the developing countries.[83] Recently, PCR has also been shown as an important diagnostic test.[84]

Treatment

Six-month tuberculosis chemotherapy is advised, although controlled clinical trials are lacking for short course chemotherapy in GUTB.[85] Adjuvant corticosteroids are recommended to avert ureteric strictures. Steroids have also been found helpful in the treatment of tuberculous interstitial nephritis.[86] Sometimes, surgery such as nephrectomy is required for the destroyed nonfunctioning kidney; partial nephrectomy ureteric stricture dilatation and bladder reconstruction may be done as per appropriate indication. A full course of chemotherapy is essential in addition to surgery.

SKIN TUBERCULOSIS

Skin tuberculosis contributes 1 to 2.5% share of all skin disease cases, the ailment is more commonly found in poor socioeconomic populations.[87-89] The skin may be involved by tuberculosis through different modes of spread.

Clinical Features

There are three main classes of skin tuberculosis determined by the presence of previous sensitization to tubercle bacilli, immune response of the host and route of inoculation by tubercle bacilli. In order of frequency, these are lupus vulgaris, tuberculosis verrucosa cutis and scrofuloderma. These three types are seen in persons, who had previously been infected with tubercle bacilli and have delayed hypersensitivity to the tubercle bacilli. In absence of previous sensitization, the disease may occur in the form of tuberculous chancres and miliary tuberculosis of skin. Tuberculids are the hypersensitivity lesions of skin, which occur as a result of tuberculosis elsewhere in the body.

Lupus vulgaris: It is the most common variety of skin tuberculosis, which is present with firm plaques that exhibit central clearing and activity on margins (Fig. 47.8). The active margins show erythematous translucent papules, popularly described as apple-jelly nodules. Most often, the lesions are dry, but sometimes seropurulent discharge and crust formation may be seen. Long-standing lesions may occasionally get complicated with squamous cell carcinoma. Usually, the lesions are encountered over the face, buttocks and lower limbs. Sometimes, underlying tuberculosis may extend in the skin as lupus vulgaris. BCG vaccination may rarely get complicated as lupus vulgaris. Often, patients do not have constitutional symptoms, and tuberculin skin test is usually positive in such cases. Typical clinical features, demonstration of mycobacterium in the smear or biopsy, classical tuberculosis granuloma and response to the therapeutic trial authenticate the diagnosis. Skin TB can be adequately treated with six-month short-course chemotherapy.[90]

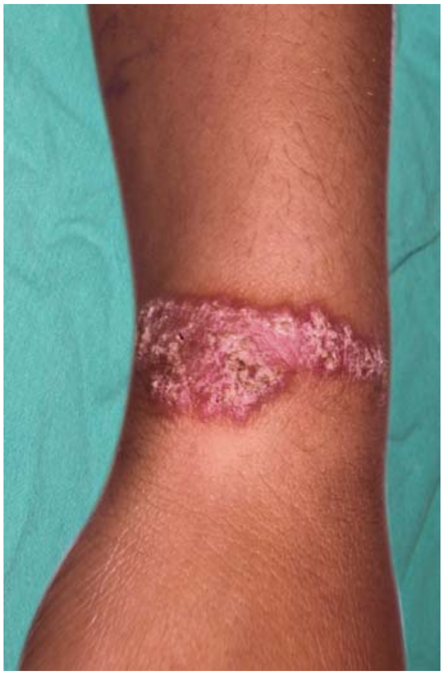

Fig. 47.8: Lupus vulgaris lesion showing central scarring and peripherally active lesion in upper limb just above the wrist

Scrofuloderma: It is the commonest form in which tuberculosis involves the skin as a direct extension of the underlying tuberculous pathology of lymph nodes, bones or urogenital tract.[91,92]

Chancre: This is a primary infection of skin, which occurs as a result of accidental inoculation of the abraded or injured skin by tubercle bacilli. Commonly, seen in the children of the family with member/s having sputum-positive pulmonary tuberculosis. Lesions are often seen on the limbs. At the outset, a papilla or a nodule develops locally, which subsequently ulcerates. Simultaneously, there occurs regional lymph node enlargement. The cutaneous lesion and regional lymphadenopathy together constitute the primary complex. Lesions usually heal spontaneously or may progress into lupus vulgaris. The biopsy of the early lesion shows neutrophils and tubercle bacilli, typical tuberculous granulomas are seen later.

Miliary TB of skin: Skin lesions, consequent upon hematogenous spread of tubercle bacilli during primary infection, often go dormant or get healed with the development of immunity. These lesions get reactivated in the form of pustules and papules, later in life whenever there occurs immunosuppression, e.g. during measles or viral infections. Usually, constitutional symptoms of tuberculosis are present along with such lesions.

Tuberculids: Four diagnostic criteria must be fulfilled to qualify for the confirmed diagnosis of tuberculids:

1. On biopsy, the lesion should have tuberculoid granuloma
2. *Mycobacterium* should not be seen in the lesion
3. Mantoux test is strongly positive
4. Treatment of underlying tuberculosis should ameliorate the tuberculid skin lesions.

There are four types of tuberculids described; lichen scrofulosorum, erythema induratum, papulonecrotic tuberculids and erythema nodosum with different morphological features (Fig. 47.9).

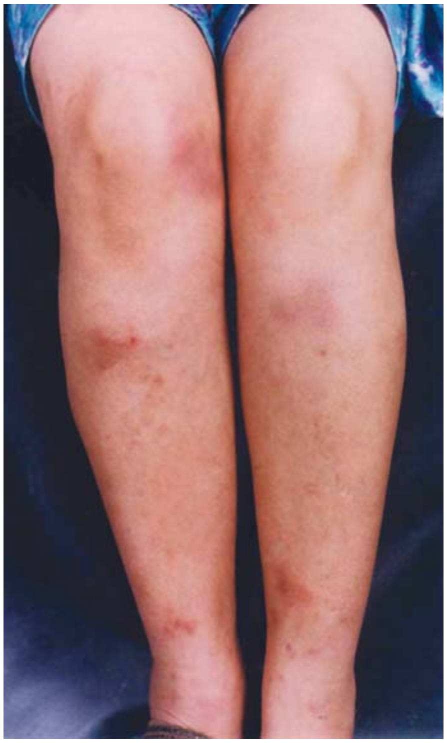

Fig. 47.9: Erythema nodosum over shin area in a 16-years-old girl suffering from tuberculous lymphadenitis

DISSEMINATED MILIARY TUBERCULOSIS

Miliary tuberculosis is a disseminated disease with discrete millet seed size tuberculous foci found homogeneously distributed in the lungs and other viscera.[15,93-96] Classical miliary mottling on chest radiograph is the familiar picture, which supports the diagnosis. It is the cryptic variant, which poses a diagnostic dilemma even in the endemic area. Sometimes, the disease may present as Acute Respiratory Distress Syndrome (ARDS), therefore, the tuberculous etiology must be kept in mind, particularly when no obvious cause is available for the same.

Pathogenesis

Commonly during the stage of hematogenous spread of primary tuberculosis, the AFB get disseminated to various viscera particularly the highly vascularized organs like the lung, liver, spleen, bone marrow and brain. The bacilli initiate the discrete tuberculous foci in these viscera. With the development of immunity and delayed hypersensitivity, these foci heal in majority of the subjects. In a few, they fail to heal and progress to acute miliary tuberculosis. In the endemic areas, the miliary TB is seen in young children, however, in the developed countries, majority of such patients are seen in the elderly patients. Miliary TB can also come up later in life when healed primary foci, after getting reactivated with caseation necrosis, erode into the blood vessels. The erosion of active focus in the blood vessel causes hematogenous embolization of tubercle bacilli giving rise to disseminated tuberculous foci all over the body. Microscopically, in an immunocompetent person, each focus represents a typical tubercle with caseation in the center comprising of Langhans type of giant cells, epithelioid cells, lymphocytes, fibrocytes and AFB. However, in immunosuppressed subjects or elderly persons, the appearance is often of nonreactive type lesions, which show necrosis teaming with tubercle bacilli, but without typical granuloma formation.

Clinical Features

The miliary tuberculosis has slight preponderance for male gender. Symptoms develop gradually, include generalized constitutional features along with spiky fever and chills. Nearly 6 to 8% of all EPTB cases are miliary TB cases. There are two main clinical variants of miliary TB viz. acute miliary and cryptic miliary.

Acute miliary TB: Over and above the constitutional features, headache may be encountered, possibly due to

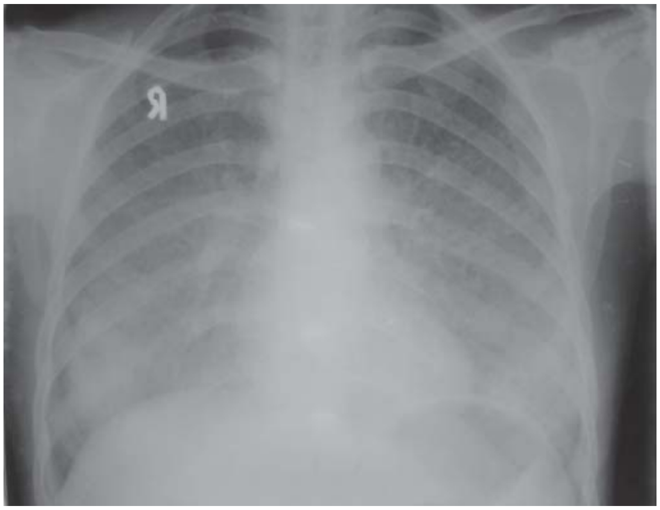

Fig. 47.10: The chest radiograph posterior-anterior view showing typical miliary tuberculosis in a young female

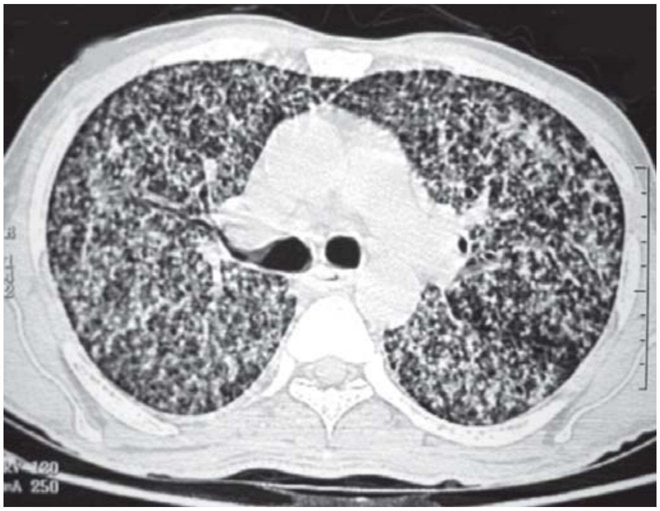

Fig. 47.11: High-resolution CT thorax shows extensive miliary nodules in both lungs

coexisting TBM, thus a lumbar puncture must be performed in patients with headache. Hemoptysis and dyspnea are not frequently seen in such cases. Hepatosplenomegaly and icterus may be present. Chest examination is unremarkable. However, minimal pleural and pericardial effusions may be seen. Fundus should be looked for choroid tubercles. The latter are seen as pale, grayish white, oblong patches frequently bilateral. In one series, they were encountered in 7.2% cases only.[97] Demonstration of choroid tubercle is highly supportive of the diagnosis of miliary tuberculosis; however, the finding is more common in children. Tuberculomas may commonly complicate miliary tuberculosis. Adrenal insufficiency has also been commonly described. The chest radiograph reveals typical miliary pattern, i.e. homogeneously distributed discrete uniform size (1–2 mm) millet-shaped lesions in all lung zones (Figs 47.10 and 47.11).

Cryptic miliary TB: Cryptic is an atypical presentation of miliary tuberculosis in which chest radiograph does not show classical miliary mottling. Usually seen in elderly patients of over 60 years of age, but may be seen in the younger age group, particularly in the endemic areas. The symptoms usually appear insidiously, include the presence of weight loss, intermittent fever, malaise and mild hepatosplenomegaly. Meningitis and choroid tubercles are very uncommon features in this variant of miliary tuberculosis. Maintaining a high index of suspicion is the only way for its timely diagnosis.

Diagnosis

Classical miliary mottling on chest radiograph is most helpful to make the diagnosis of miliary tuberculosis, the same may not be seen in early stages or in the cryptic miliary variant. In such situations, characteristic picture on HRCT is very helpful. Sometimes, chest radiograph picture like that seen in ARDS or acute lung injury and shadows larger than usual miliary mottling are also encountered. For confirmation of diagnosis, all efforts must be made to isolate tubercle bacilli from various specimens such as sputum, pleural fluid, CSF, urine, BAL fluid, blood and histopathological samples. Tuberculin skin test is often negative. In one series, tuberculin anergy was reported in 68% cases of miliary TB.[98]

Blood dyscrasias like pancytopenia and leukemoid reactions are commonly seen in the cryptic form of miliary tuberculosis. Sometimes, bone marrow examination is required, particularly in the presence of leukemoid reaction. Bone marrow aspiration may reveal granulomas or even *Mycobacterium tuberculosis*. Liver biopsy provides the highest yield, granulomas have been reported in up to 75% cases. In unconfirmed cases, particularly when the patient is not willing for invasive procedure, therapeutical trial with antituberculosis drugs must be given. With the initiation of tuberculosis drugs, fever usually subsides within 7–10 days, over all clinico-radiological improvement is appreciated in four to six weeks of treatment. Early diagnosis is imperative for favorable outcome of treatment of miliary tuberculosis, which is uniformly fatal, if untreated.[98,99]

Treatment

In principle, the standard six-month treatment for pulmonary tuberculosis is adequate for miliary tuberculosis also. The standard regimens comprise of initial two month intensive phase of isoniazid, rifampicin, pyrazinamide and ethambutol (or streptomycin) followed by four months continuation phase of isoniazid plus rifampicin. Nine-months regimen is recommended in infants and children.[100] Unequivocal evidence is lacking for the use of corticosteroid in the treatment of miliary tuberculosis.

PERICARDIAL TUBERCULOSIS

Tuberculous involvement of pericardium is usually secondary to tuberculosis elsewhere in the body. Nearly 1 to 8% of pulmonary tuberculosis patients have concomitant pericardial tuberculosis. Of all acute pericarditis, about 4% in developed countries and 60 to 80% cases in the developing countries are in fact tuberculous in origin.[101,102]

Pathogenesis

Direct extension from tuberculous mediastinal lymphadenitis is the commonest route for the involvement of pericardium. The infection may also reach pericardium through lymphatic and hematogenous routes from tuberculosis of the lungs, kidneys, bones or other organs. Pericardial tuberculosis has following four pathological stages: 1. dry pericarditis; 2. effusive pericarditis; 3. absorptive, and 4. constrictive pericarditis stage. Patient may present during any stage of pathological progress. Invariably, the pericardial fluid is straw colored and exudative type; very rarely there could be frank pus in the pericardium due to intense inflammation. The pericardium may contain somewhere between 15 ml and 3500 ml of fluid. When the fluid collection occurs at very rapid rate, the patient may develop cardiac tamponade. With in a few weeks of development of pericardial effusion, there occurs thickening especially of the visceral pericardium resulting into effusive constrictive pericarditis. In the absence of effective antituberculous therapy, continued fibrosis may lead to chronic constrictive pericarditis. Complete obliteration of pericardium due to fibrosis interferes with the proper cardiac functioning. Sometimes, the disease may involve the myocardium, ultimately leading to myonecrosis and muscle atrophy. Around 15% of patients show pericardial calcification, but it is reported in around 75% in some studies.[103,104]

Clinical Features

The disease is usually seen during third to fifth decades of life. Gradual onset tuberculous toxemia with anorexia, weight loss, malaise, low-grade evening temperature, and early fatigability is usually present. In around 20% cases, pericardial effusion may present as acute cardiac tamponade with tachycardia, high jugular venous pressure and feeling of retrosternal compression. Shortness of breath, chest pain and edema feet may be seen in around 40 to 70% cases.[105-107] Cardiac auscultation reveals muffled heart sounds and pericardial rub. Echocardiography is an important aid to confirm the diagnosis. Effusive-constrictive pericarditis patients usually show cardiomegaly, edema feet and elevated jugular venous pressure. In chronic constrictive pericarditis, there occurs the impediment of venous return due to tough encasement of the heart; however, heart shape and size remain normal. This causes pulmonary and systemic congestion leading ultimately to shortness of breath, orthopnea with edema, ascites and pulsus paradoxus. Long-standing elevation of venous pressure may cause protein-losing enteropathy and resultant hypoproteinemia. Ascites is more prominent, called ascites praecox.[108]

Diagnosis

Idiopathic or viral pericarditis is a common condition, which needs to be distinguished from tuberculous pericarditis. The former conditions are usually acute in onset, have minimal or no effusion, and are self-limiting in two to three weeks. On the contrary, more prolonged course and large effusions are frequent in tuberculous pericarditis. Chest radiograph may reveal cardiomegaly, pericardial calcification and pulmonary disease. Whenever associated with pulmonary tuberculosis, sputum must be examined for tubercle bacilli. ECG changes of acute pericarditis, such as ST elevation were seen in only 10% cases in some studies.[106,109] Echocardiography is a good test for detecting effusion and cardiac tamponade, although, not very accurate in picking up pericardial thickening. CT and MRI are other important adjuncts in helping the diagnosis.[110] Pericardiocentesis is performed for diagnostic tests of the fluid as well as for therapeutic purpose in cardiac tamponade. Pericardiocentesis should preferably be done under echocardiography employing apical approach. Pericardial fluid characteristics are exactly the same as encountered in tuberculous pleural effusion as far as physical, cellular, tubercle bacilli isolation, or ADA level are concerned, the same diagnostic standards are applicable.[111] Pericardial tissue taken by open biopsy may reveal typical granulomas with caseation necrosis in around 60% cases.

Treatment

If not treated, the disease is almost always fatal; even with treatment the mortality is 3 to 14%. Medical treatment using standard six-month short-course tuberculosis chemotherapy is successful in achieving the cure.[103,112] Addition of corticosteroids has been found associated with reduction in the frequency of pericardiocentesis and mortality.[103,112,113] Therefore, all patients of tuberculous pericarditis, barring contraindications should get 40–60 mg of prednisolone daily for four to six weeks with subsequent tapering over a five-week period. Pericardiocentesis is life-saving in cardiac tamponade, but recurrent effusion may require pigtail catheter placement. Some cases may require pericardiotomy, cardiopulmonary bypass may be necessary in cases with extensive calcification.[37]

HEPATIC TUBERCULOSIS

Hepatic tuberculosis is relatively uncommon form of extrapulmonary tuberculosis. It is secondary to pulmonary or gastrointestinal tuberculosis. Hepatic involvement has been reported in 10 to 15% of patients with pulmonary tuberculosis, and commonly found in patients with disseminated tuberculosis.[114] Hepatic tuberculosis generally occurs due to the reactivation of an old tuberculous focus, or on rare occasions as a result of a primary hepatic infection.[115,116] Tubercle bacilli reach the liver by way of hematogenous dissemination; the portal of entry in case of miliary tuberculosis is through the hepatic artery whereas in the case of focal liver tuberculosis, it is via the portal vein. The tuberculous liver abscess is an uncommon presentation in patients with hepatic tuberculosis.[115]

The clinical diagnosis of hepatic tuberculosis is difficult. Usually, symptoms and signs in this condition are nonspecific. Other than the constitutional symptoms, abdominal pain is present in 65 to 87% and jaundice in 20 to 35% patients. The jaundice may be caused by extra- or intrahepatic biliary obstruction.[117] Hepatomegaly is frequently encountered. The laboratory investigations frequently reveal increase in alkaline phosphatase with normal transaminases.[118] Ultrasonography finding of tuberculous liver abscess consists of a hypoechoic mass lesion in the liver, CT scan findings show a hypodense lesion with peripheral enhancement and central nonenhancing necrotic area.[114] The definitive diagnosis of tuberculous liver abscess needs microbiological and pathological examination of the specimen from the abscess. Aspiration of the liver lesion under the guidance of USG or CT can provide a precise specimen for confirmation.

Hepatic tuberculosis is treated with similar six-month regime (2HRZE/S, 4HR) as for other forms of tuberculosis. It is only occasionally that drainage is required for a large abscess. Most of the lesions, including the abscess will resolve with chemotherapy, provided an early treatment is instituted.

Multidrug-Resistant Tuberculosis

Surendra K Sharma, Ninoo George

INTRODUCTION

Tuberculosis (TB) is the leading cause of death among curable infectious diseases.[1] TB remains a significant global health concern, despite the substantial progress made over the past decades in TB control activities in various countries.[2, 3] The number of TB cases that occurs each year in the world are still growing, although the rate of increase is slowing.[2] One of the most worrisome elements of the TB pandemic is the global emergence and spread of drug-resistant strains of TB.[4,5] The emergence of Multidrug-resistant TB (MDR-TB) and Extensively drug-resistant TB (XDR-TB) have dampened all enthusiasm in controlling and eliminating TB globally. Drug-resistant TB commonly arises through the selection of mutant strains, usually due to inadequate chemotherapy.[6] Treatment of drug-resistant TB requires prolonged and expensive chemotherapy using second-line drugs that are more toxic and less efficacious. The only way to control and eventually eliminate TB is through a concerted attempt by health care providers, health administrators, funding agencies and commitment of the individual clinicians treating those patients.[7]

EPIDEMIOLOGY

There were an estimated 9.2 million new cases of TB in the world in 2006 (139 per 1,00,000 population) and out of these, 4.1 million cases were of sputum-positive pulmonary TB (44% of the total).[8] It is estimated that 4,89,139 cases of MDR-TB emerged in 2006 and the global proportion of MDR-TB among all TB cases was 5.3%.[9] It is ironical that drug resistance develops and flourishes in those settings that are least able to deal with it. China and India carry approximately 50% of the global burden and the Russian Federation carries a further 7%.[9] In terms of proportion, the countries of the former Soviet Union are facing a serious and widespread epidemic, where almost half of all TB cases are resistant to at least one drug and every fifth case of TB have MDR-TB.

Studies conducted in India have found MDR-TB rates of 0.14 to 5.3% among new cases[10-21a] and 12.8 to 49% among previously treated cases.[15,22-28a] The fourth global report of the World Health Organization (WHO) states a prevalence of 2.8% among new cases and 17.2% among treated cases in India.[9] These data, although not representative of the entire population, provide a fairly decent estimate of the rate of drug-resistance among new and previously-treated TB cases in India. Tables 48.1 and 48.2 show the prevalence of MDR-TB, reported in various studies from India among new and previously treated cases, respectively.

The XDR-TB outbreak in KwaZulu-Natal, South Africa, in 2006 caught global attention on this deadly form of TB.[29] As of June 2008, 49 countries have reported confirmed XDR-TB cases to the WHO; XDR-TB has been found in all areas wherever it has been tested.[30] The situation is grim because the facility for second-line drug susceptibility testing (DST) is available only in few centers across the world and the real burden of XDR-TB is unknown. It has been estimated that 10% of all MDR-TB strains identified across six continents were actually XDR-TB.[31] XDR-TB has also been reported from different parts of India. The prevalence of XDR-TB among MDR-TB has varied from 1.5 to 33% in various studies from different parts of India[32-37] (Table 48.3).

DEFINITION

MDR-TB is defined as TB caused by bacilli showing resistance to isoniazid and rifampicin with or without resistance to other antituberculosis drugs. XDR-TB is defined as TB caused by bacilli showing resistance to isoniazid and rifampicin, in addition to any of the fluoroquinolones and to at least one of the three following injectable drugs, viz amikacin, kanamycin or capreomycin.[38]

Drug-resistance in TB may be broadly classified as primary or acquired.[39] When drug-resistance is demonstrated in a patient who has never received antituberculosis treatment previously, it is termed as primary resistance. Acquired resistance is one that results due to specific previous treatment. However, the WHO and the International Union Against Tuberculosis and Lung Diseases (IUATLD) have replaced the term primary resistance by the term "drug resistance among new cases" and acquired resistance by "drug-resistance among previously treated cases".[40]

CAUSES OF DRUG RESISTANCE

Previous treatment for TB is the most important risk factor for the development of MDR-TB.[6] Inadequate previous treatment exerts selection pressure and favors the multiplication of resistant tubercle bacilli, which eventually become the dominant population. Bacilli, which initially had resistance to only one drug may soon develop resistance to two drugs and then sequentially to many drugs. The potential causes of inadequate drug treatment are summarized in Table 48.4 and the mycobacterial genes involved in drug resistance are shown in Table 48.5. In addition to these, bacterial virulence factors (e.g. W-Beijing genotype[41]) and host

TABLE 48.4: Causes of inadequate treatment of tuberculosis

Causes	*Description*
Providers/Programs: Inadequate regimens	Inappropriate guidelines Noncompliance with available guidelines Absence of guidelines Poor training No monitoring of treatment Poorly organized or funded TB control programs
Drugs: Inadequate supply/quality	Poor quality Unavailability of certain drugs (stock-outs or delivery disruptions) Poor storage conditions Wrong dose or combination
Patients: Inadequate drug intake	Poor adherence (or poor direct observation of treatment) Lack of information Lack of money (No free treatment available) Lack of transportation Side effects Social barriers Malabsorption Substance abuse disorders

TABLE 48.5: Antituberculosis drugs and genes involved in their resistance

Drug	*Genes involved in drug resistance*
Isoniazid	Enoyl-acyl carrier protein (ACP) reductase (InhA) Catalase-peroxidase (katG) Alkyl hydroperoxide reductase (AhpC) Oxidative stress regulator (oxyR) β-ketoacyl-acyl carrier protein synthase (kasA)
Rifampicin	RNA polymerase subunit B (rpoB)
Pyrazinamide	Pyrazinamidase (PncA)
Streptomycin	Ribosomal protein subunit 12 (rpsL) 16s ribosomal RNA (rrs) Aminoglycoside phosphotransferase gene (strA)
Capreomycin	Hemolysin (HlyA)
Ethambutol	Arabinosyltransferase (emb A, emb B and emb C)
Fluoroquinolones	DNA gyrase (gyr A and gyr B)

genetic factors[42] may also contribute to drug resistance. The presence of HLA-DRB1*14, DQB1*0503 and DQB1*0502 alleles were found to be significant risk factors for the development of MDR-TB.[42]

Another important concern is that the nation-wide emergence of MDR-TB has led to the widespread use of second-line drugs, mainly by the private sector. Second-line drugs are freely available over the-counter and there is no control on the purchase and use of these drugs by patients or practitioners. No data exist regarding treatment practices in the private sector or medical colleges for patients with diagnosed or suspected cases of drug-resistant TB. This has already led to the development and spread of XDR-TB in India.

DIAGNOSIS OF DRUG-RESISTANT TB

MDR-TB and XDR-TB are pure laboratory diagnoses. The diagnosis of drug-resistant TB requires isolation and culture of the tubercle bacilli followed by DST in a quality-assured, accredited laboratory. The laboratory capacity is limited in regions like India, Sub-Saharan Africa and South-East Asia where the burden of MDR-TB and XDR-TB is high, resulting in serious diagnostic challenges. The Supranational reference laboratory network (SRLN) was formed in 1994 to ensure optimal performance and quality assurance of the laboratories engaged in DST of anti-TB drugs. The network has expanded since 2004 and now includes 26 laboratories in six WHO regions and is coordinated by the Prince Léopold Institute of Tropical Medicine in Antwerp, Belgium.[9]

Lack of Adequate Laboratory Infrastructure

DST for antituberculosis drugs is highly prone to laboratory errors and hence requires laboratories that are subjected to continuous internal quality control and periodic external quality assurance.[43] Otherwise, overdiagnosis may impose unnecessary financial burden on the country and drug toxicity on the patient, whereas underdiagnosis may lead to undertreatment of the patient leading to further drug resistance, treatment failure and spread of resistant strains to others. Till date, there are serious laboratory constraints due to lack of adequate infrastructure, technical manpower and finances. In India, the SRLN is located at Tuberculosis Research Centre (TRC), Chennai and this is the only laboratory in India that is accredited to perform second-line DST.[43] There is an urgent need for rapid scaling up of the laboratories to ensure proper diagnosis and management of MDR- and XDR-TB.

Delay in Diagnosis

Field diagnosis of MDR-TB is not possible at present and requires transportation of the patient's sputum to the

Intermediate reference laboratory (IRL) for diagnosis. In the IRL, culture is done on Lowenstein-Jensen medium and DST is carried out using the proportion method, which is considered to be the gold standard.[43] Cultures are very slow growing and often take 6 to 8 weeks to complete. Preliminary results from DOTS plus program in Gujarat and Maharashtra show that the average time delay for processing the sputum sample and getting back the DST results is at least three months.[44] During this time, patients may be inappropriately treated, drug-resistant strains may continue to spread and amplification of resistance may occur. In Gujarat, 20 out of 175 MDR-TB patients died prior to initiation of category IV regime while waiting for the DST results. Alarming reports of potential nosocomial transmission and rapid mortality in patients with HIV coinfection[29] have highlighted the need for rapid screening methods.

The Hain GenoType® MTBDR plus assay is a multiplex PCR line-probe assay that detects mutations in the rpoB gene for rifampicin resistance, the katG gene for high-level isoniazid resistance and the inhA gene for low-level isoniazid resistance, directly from smear-positive sputum. Results are available within one day.[45,46] This molecular assay is a highly accurate screening tool for MDR-TB and achieves a substantial reduction in diagnostic delay.

MANAGEMENT

No randomized controlled trial exists to address the issue of optimal management strategy for MDR-TB. The management of MDR-TB and XDR-TB is associated with numerous challenges.[47]

Pretreatment Evaluation and Counseling

Once the diagnosis of MDR-TB or XDR-TB is confirmed, the first challenge is to disclose the diagnosis to the patient and counsel the patient. Various issues need to be discussed like the nature of the disease, the nature of treatment he/she is about to undergo, the duration of treatment, the possibility of Adverse drug reactions (ADR), the need for strict adherence to treatment, the need for daily injections for at least 6 to 9 months and need for initial/subsequent hospitalization if needed. It is advisable to involve close family members during the counseling, since family support is an essential component in the management. Female patients should receive special counseling on family planning. The patients should be screened for comorbidities like diabetes mellitus, liver disease, renal insufficiency, drug or alcohol use, HIV, mental illness, thyroid disorders, pregnancy and lactation.

Treatment Strategy

Three different strategies can be used in the management of drug-resistant TB, viz: i. standardized treatment, ii. empirical treatment, or iii. individualized treatment.[48] Standardized treatment refers to the use of a fixed combination of drugs for treating all patients. The regimen is usually based on the DST profile of the population at large. Empirical treatment, on the other hand, uses those drugs to which the individual has not been previously exposed or received for less than one month and hence, presumed to be effective. Individualized treatment, on the other hand, is based on individual DST results and uses only those drugs with proven in vitro susceptibility. Initiation of an empirical regimen till DST results are available and then switching over to an individualized regimen is probably the best strategy to achieve the highest cure rates. Table 48.6 summarizes the basic differences between standardized and individualized regimes.

TABLE 48.6: Difference between standardized and individualized regimen

Standardized regimen	*Individualized regimen*
Same treatment regimen for all cases	Individualized regimen for each case
Based on representative DST of whole population	Based on previous H/O ATT and individual DST results. Uses the most effective drugs against the particular strain
Easier to implement on a programmatic scale	Difficult to implement on a programmatic scale
Low cure rates	Better cure rates
Cost and duration predictable	Expensive and duration may be extended based on lack of response

Designing an Appropriate Regimen

The exact number of drugs that are needed to cure MDR-TB and prevent the creation of further drug resistance is unknown.[4] Most studies had used regimens containing four to six second-line drugs, a prudent approach has given the high bacillary burden and chronic lesions among patients and the poor potency and penetration of second-line drugs.[49,50] The recommended duration of treatment is guided by smear and culture conversion. The minimal recommendation is that treatment should lasts for at least 18 months after culture conversion. Extension to 24 months may be indicated in patients with extensive pulmonary damage.[48]

The DOTS plus recommends the use of Standardized Treatment Regimen (STR) under the RNTCP program, comprising of 6 drugs (kanamycin, ofloxacin, ethionamide, pyrazinamide, ethambutol and cycloserine) during 6 to 9 months of the intensive phase and 4 drugs (ofloxacin, ethionamide, ethambutol and cycloserine) during the 18 months of the continuation phase.[43]

P-aminosalicylic acid (PAS) is included in the regimen as a substitute drug if any bactericidal drug (K, Ofl, Z and Eto) or any 2 bacteriostatic (E and Cs) drugs are not tolerated, but one must remember that extrapolating this standardized regimen to complicated, individual cases may result in treatment failures. The DOTS-plus program has been initiated in pilot phase in Gujarat and Maharashtra. Preliminary data from Gujarat shows encouraging results. Of 116 patients who have been placed on Category IV regime, 60 patients had completed nine months of treatment. In this cohort of 60 patients, 88.3% had achieved smear conversion and 68.3% had achieved culture conversion at the end of nine months.[44]

Studies that have achieved cure rates of more than 75% highlight the importance of using sufficient number of drugs at the highest possible dosages for the maximum duration.[49,50] An aggressive approach right from the start can help in achieving better outcomes. Table 48.7 summarizes the lessons learnt from these studies. These principles have to be adhered, when designing regimens for MDR or XDR-TB, to achieve the best possible outcomes.

TABLE 48.7: Lessons learnt from previous studies on MDR and XDR-TB that had achieved high cure rates

- Treat aggressively
- Use at least four drugs presumed to be effective
- Use the highest possible doses, limited only by adverse drug reactions
- Give drugs for the maximum possible duration
- Include as many first-line drugs as possible (especially in XDR-TB), even if *in vitro* susceptibility is absent
- Fluoroquinolones and aminoglycosides should be a part of any regimen
- Use later-generation fluoroquinolones, if there is resistance to earlier fluoroquinolones
- Use capreomycin if there is resistance to amikacin or kanamycin
- Use adjuvant drugs if there is inadequate response/marked drug resistance
- Use resective thoracic surgery in patients with inadequate response or treatment failure associated with limited disease and good pulmonary reserve.

Drugs for MDR-TB and XDR-TB

Table 48.8 gives a list of drugs available to treat MDR- and XDR-TB. Currently available second-line drugs used to treat MDR and XDR-TB are four to ten times more likely to fail than standard therapy for drug susceptible tuberculosis.[4] Many health care providers have little or no experience with second-line drugs and their side effects, especially in combinations of 4 to 6 at a time. Most second-line drugs have a short shelf life, global production of quality assured drugs is limited and drug registration may be a lengthy and costly process that is not always attractive to drug manufacturers.[43] In addition, drugs may need to be changed often due to side effects, delayed DST results and poor response to treatment. After the introduction of rifampicin, no worthwhile antituberculosis drug with new

TABLE 48.8: Drugs to treat MDR and XDR-TB and their recommended dosages

Drug	*Daily dosage*
Aminoglycosides	
Streptomycin	15 mg/kg (750–1,000 mg)
Kanamycin	15 mg/kg (750–1,000 mg)
Amikacin	15 mg/kg (750–1,000 mg)
Capreomycin	15 mg/kg (750–1,000 mg)
Thioamides	
Ethionamide	10–20 mg/kg (500–750 mg)
Prothionamide	10–20 mg/kg (500–750 mg)
Pyrazinamide	20–30 mg/kg (1,200–1,600 mg)
Fluoroquinolones	
Ofloxacin	7.5–15 mg/kg (600- 800 mg)
Levofloxacin	500–1000 mg
Moxifloxacin	400 mg
Ethambutol	15–20 mg/kg (1,000–1,200 mg)
Cycloserine†	15–20 mg/kg (500–750 mg)
Terizodone†	15–20 mg/kg (600 mg)
Para-aminosalicylic acid	150 mg/kg (10–12 g)

mechanism(s) of action has been developed in over thirty years, but many newer agents are under development and some are already in clinical trials. Table 48.9 gives a list of these newer antituberculosis agents. Among these, the nitroimidazopyran PA-824 and the diarylquinoline TMC207 (previously R207910) are promising new agents.[51,52]

The diarylquinoline TMC207 offers a new mechanism of antituberculosis action by inhibiting mycobacterial ATP synthase. A recent phase II randomized placebo-controlled trial compared the efficacy and safety of this agent in combination with standard five-drug, second-line antituberculosis regimen.[53] The addition of TMC207 to standard therapy for MDR-TB reduced the time to conversion to a negative sputum culture, as compared with placebo and increased the proportion of patients with conversion of sputum culture (48% vs 9%). Most adverse events were mild to moderate and only nausea occurred significantly more frequently among patients in the TMC207 group than among patients in the placebo group (26% vs 4%). Another multicenter international trial, involving our center, is ongoing to evaluate the safety and efficacy of TMC207 in MDR-TB (NCT00449644).

The role of linezolid in drug-resistant, TB has evoked considerable interest. Although *in vitro* studies have shown the good activity of linezolid against different species of mycobacteria, clinical experience with the use of linezolid in the management of mycobacterial infections is still sparse. Some case series have reported good efficacy of linezolid against MDR and XDR-TB.[54,55] Studies have shown that linezolid (600 mg twice daily in adults) is safe and generally well tolerated for courses of therapy of less than 28 days, but long-term linezolid use has been associated with reversible hematopoietic suppression, primarily thrombocytopenia and neuropathy.[56,57] Undoubtedly, linezolid is a valuable drug to the armamentarium of antituberculosis agents, but long-term studies are required to conclusively prove the efficacy and safety of linezolid in MDR and XDR-TB.

Adverse Drug Reactions

Adverse drug reactions are an important cause of poor compliance and default.[58] Adverse drug reactions sometimes warrant stoppage of the offending drug and further curtail drug options. Even in short-course chemotherapy for drug sensitive TB, side-effects, such as hepatitis, dyspepsia, skin reactions and arthralgia were responsible for the termination of therapy in up to 23% of patients during the intensive phase.[59] The side-effect profile of TB chemotherapy is magnified in patients with concurrent HIV infection or prior history of hepatitis,[60] and those being treated with second-line drugs for MDR-TB, during which as many as 86% of patients may develop medication side-effects.[61] Table 48.10 gives a list of the common adverse-drug reactions encountered during treatment of MDR and XDR-TB.

To minimize the adverse impact of medication side-effects in treatment adherence, it is important that TB health staffs are adequately trained on their recognition and management. It is also important that medications for managing side-effects should be ordered concurrently with the ordering of anti-TB chemotherapy to facilitate timely and adequate treatment of such side effects.

Follow-up and Monitoring

Close follow-up and monitoring is mandatory for patients with MDR and XDR-TB to ensure strict compliance to the regime, prompt identification and management of adverse drug reactions and early detection and treatment of treatment failure. Directly Observed Treatment (DOT) is integral for close follow-up and monitoring.[43] Monitoring of patients on MDR- and XDR-TB treatment requires not only careful clinical examination, but also appropriate laboratory investigations like chest radiographs, renal and liver function tests, serum electrolytes and thyroid profile at appropriate time intervals for prompt identification of adverse reactions.

Follow-up sputum smear and culture schedule during treatment is as follows: Four sputa are to be

TABLE 48.10: Common adverse events of drugs used in MDR and XDR-TB

Drug	*Adverse event(s)*
Aminoglycosides	
Streptomycin	Pain at injection site, ototoxicity (vertigo and deafness), nephrotoxicity, hemolytic anemia, aplastic anemia, agranulocytosis, thrombocytopenia, and lupoid reactions
Kanamycin	
Amikacin	
Capreomycin	Hypokalemia, hypocalcemia and hypomagnesemia, cutaneous reactions and occasionally hepatotoxicity
Thioamides	
Ethionamide	Epigastric discomfort, anorexia, nausea, metallic taste and sulfurous belching, vomiting and excessive salivation; psychotic reactions including hallucinations and depression; hypoglycemia, hypothyroidism and goiter; hepatotoxicity; gynecomastia, menstrual disturbance, impotence, acne, headache and peripheral neuropathy; tolerance varies with ethnicity; usually well tolerated in Africa and Asia
Prothionamide	
Pyrazinamide	Hepatotoxicity, GI intolerance, hyperuricemia and arthralgias
Fluoroquinolones	
Ofloxacin	Uncommon GI disturbance (e.g. anorexia, nausea, vomiting), CNS symptoms (e.g. dizziness, headache, mood changes and rarely convulsions), QT interval prolongation
Levofloxacin	
Moxifloxacin	
Ethambutol	Dose-dependent optic neuritis and peripheral neuritis
Cycloserine	Dizziness, slurred speech and convulsions
Terizodone	Headache, tremor, insomnia, confusion, depression and altered behavior, suicide risk, generalized hypersensitivity reaction or hepatitis
Para-aminosalicylic acid	GI disturbance (e.g. anorexia, nausea, vomiting, abdominal discomfort and diarrhea), general skin or other hypersensitivity, and hepatic dysfunction, hypokalemia, hypothyroidism and goiter; best avoided in renal failure as it may exacerbate acidosis; sodium salt should not be given when a restricted sodium intake is indicated
Linezolid	Hematological (anemia, thrombocytopenia), peripheral neuropathy
TMC207	Nausea, QT interval prolongation

collected and examined by smear and culture at least thirty days apart from 3rd to 7th month of treatment (i.e. at the end of the months 3, 4, 5, 6 and 7) and at 3-month intervals from the 9th month onwards till the completion of treatment (i.e. at the end of the months 9, 12, 15, 18, 21 and 24).[43] The importance of the sputum examination during treatment needs to be emphasized, since the most important objective evidence of improvement is the conversion of sputum smear and culture to negative.

Patients will be considered culture converted after having two consecutive negative cultures taken at least one month apart. Patients who remain culture positive despite nine months of regular treatment are suspects of treatment failure and DST for second-line drugs should be done. An MDR-TB patient who has completed treatment and has been consistently culture negative with at least five consecutive negative results in the last 12 to 15 months is considered to be cured. If one follow-up positive culture is reported during the last three quarters, patient will still be considered cured, provided this positive culture is followed by at least three consecutive negative cultures, taken at least 30 days apart, provided that there is clinical evidence of improvement.[43]

ROLE OF IMMUNOTHERAPY

Various modalities have been tried to enhance the immune system of the body to fight off the tubercle bacillus. Favorable results were observed when immuno-enhancement using *Mycobacterium vaccae* vaccination was used to treat drug-sensitive pulmonary TB patients in Africa,[62] but very few studies have been conducted in drug-resistant TB patients to support its use.[63] Studies have shown that adjuvant therapy with *Mycobacterium welchii* vaccination along with anti-TB drugs was well-tolerated and facilitated early sputum conversion.[64,65] Aerosolized IFN-gamma, granulocyte-macrophage colony-stimulating factor, aerosolized IFN-alpha and low-dose recombinant human interleukin-2 have all been used as adjunctive therapy in the treatment of MDR-TB with conflicting results.[4] Although no definite recommendations are possible at this juncture, trials are ongoing and immunotherapy stands as a promising agent of the future.

RESECTIVE THORACIC SURGERY

The use of resective thoracic surgery alone or as a part of comprehensive treatment strategy has been shown to be associated with improved outcomes in drug-resistant TB.[66,67] Various surgical procedures have been performed in patients with MDR-TB ranging from segmental resection to pleuropneumonectomy. A combined medical and surgical approach is increasingly being used to treat patients with MDR-TB. The cure rate with surgical resectioning as an adjunct to medical therapy approximates 83 to 93% in some published series.[68,69] The principle behind surgical treatment is that it reduces the bacterial burden by resecting cavitary lesions or destroyed lobes. It is important to note that at least three months of treatment should be given before surgery, if feasible.

Indications for surgery in patients with MDR-TB include: (i) persistence of culture-positive MDR-TB despite extended drug retreatment, (ii) extensive patterns of drug resistance that are associated with treatment failure or additional resistance, (iii) local cavitary, necrotic/destructive disease in a lobe or region of the lung that is amenable to resection without producing respiratory insufficiency and/or severe pulmonary hypertension.

Surgery for TB requires highly experienced surgeons, as well as appropriate preoperative and postoperative care, trained support personnel and specialized facilities with the availability of safe blood transfusion services. Specialized facilities should also include stringent infection control measures since infectious substances and aerosols are generated in large quantities during surgery and during mechanical ventilation and postoperative pulmonary hygiene manipulations.

NUTRITIONAL SUPPORT

In addition to cause malnutrition, MDR-TB can be exacerbated by poor nutritional status, low body mass index and severe anemia.[48] Without nutritional support, patients can become enmeshed in a vicious cycle of malnutrition and disease. The second-line drugs may also further decrease the appetite, making adequate nutrition a greater challenge. Vitamin B_6 100 mg/day should also be given to all patients receiving cycloserine or terizidone to prevent adverse neurological effects.

Vitamin D has been shown to be involved in the host immune response towards *Mycobacterium tuberculosis*. Vitamin D was used for the treatment of TB in pre-antibiotic era.[70,71] Observational studies have found an association between vitamin D deficiency and active TB.[72,73] Vitamin D is a low-cost intervention that is easy to administer in resource-poor settings. The possible postulated mechanisms are that 1, 25-dihydroxy vitamin D induces anti-mycobacterial activity in macrophages by triggering antimicrobial peptides, such as cathelicidin,[74] but a recent randomized controlled trial has shown that vitamin D does not improve clinical outcomes or mortality in patients with TB.[75]

SPECIAL SITUATIONS

TB-HIV coinfection, pregnancy, breastfeeding, renal insufficiency, and liver, CNS, psychiatric and substance abuse disorders complicate the management of drug-resistant TB.

TB-HIV Coinfection

It is estimated that in India, almost 50% of individuals with HIV will develop TB during their disease course making it the most common opportunistic infection in our country.[76] HIV infection per sec does not appear to predispose a person to MDR-TB. Studies have shown that drug-resistant TB, including MDR-TB is not more common among HIV-infected persons compared to the general population.[77,78] Despite this, theoretically speaking HIV-infected individuals have a greater chance of developing MDR-TB due to the following reasons (i) increased susceptibility to TB, (ii) increased risk of nosocomial transmission, (iii) increased risk of treatment failure due to lack of compliance, drug interactions and malabsorption.

On the other hand, the mortality of drug-resistant TB in HIV-infected individuals is much higher than that of non-HIV infected individuals. The complexity and lethality of drug-resistant TB-HIV coinfection was shown in a recent study in South Africa, in KwaZulu-Natal province where 52 out of 53 HIV patients with XDR-TB died with a median survival of only 16 days from the time of diagnosis.[29]

Pregnancy

All female patients of childbearing age should be tested for pregnancy upon initial evaluation. Birth control is strongly recommended for all non-pregnant women receiving therapy for drug-resistant TB. Hamedeh and Glassroth reviewed the literature concerning over 2,000 pregnancies in mothers with TB and found no significant difference in side-effects in these women compared with non-pregnant subjects and no higher incidence of fetal abnormalities.[79] TB in pregnancy poses special challenges due to three issues. First is the use of chest radiography for diagnosis or follow-up risks radiation exposure to the developing fetus. Second, active TB per sec can lead to adverse outcomes in both mother and fetus. Third, the fetus is at the risk of teratogenic effects. Since the majority of teratogenic effects occur in the first trimester, therapy may be delayed until the second trimester, considering the severity of the underlying disease. Aminoglycosides can be toxic to the developing fetal ear and should be avoided. Ethionamide has been shown to be teratogenic in animals and should be avoided.

Breastfeeding

In lactating mothers on treatment, most antituberculosis drugs will be found in the breast milk in concentration that would equalize only a small fraction of the therapeutic dose used in an infant. However, any effects on infants of such exposure during the full course of MDR-TB treatment have not been established. Therefore, when resources and training are available, it is recommended to provide infant formula options as an alternative to breastfeeding. The mother and her baby should not be completely separated. However, if the mother is sputum smear-positive, the care of the infant should be left to family members until she becomes sputum smear-negative, if this is feasible. When the mother and infant are together, this common time should be spent in well-ventilated areas or outdoors. In some settings, the mother may be offered the option of using a surgical mask or an N-95 respirator until she becomes sputum smear-negative.

Tuberculosis in Prisons

Since early 1990s, TB outbreaks in prisons have been reported in many countries in Eastern Europe and TB strains transmitted in prisons are more likely to be drug-resistant or associated with HIV coinfection. A recent survey found a mean TB notification rate of 232 per 1, 00,000 prisoners in Europe, the highest rates being in Kazakhstan (17,808) and Azerbaijan (3,944).[80] A higher proportion of TB patients among prisoners had MDR strains than those outside prison. A cross-sectional survey was undertaken of 600 patients in Russia (309 civilians, 291 prisoners) with pulmonary TB from 2001-2002. Prevalence of MDR-TB was 37% in new prison cases and 55% in previously treated cases compared to that of 20% and 46% in civilian cases, respectively.[81]

Prisons are high-risk environments for TB transmission because of overcrowding, poor nutrition, poor ventilation and limited access to often insufficient health care. Moreover, prisoners do not represent a mere cross-section of society in general. Prisoners who are overwhelmingly male, are typically aged 15–45 years and come predominantly from poorly educated and socioeconomically deprived sectors of the population where TB infections and transmissions are higher.[82] Prisoners are also more likely to suffer from other debilitating diseases and have additional health problems such as drug addiction, alcoholism and liver disease. All these pose challenges to management and lead to poor outcomes in TB in prisons.

Tuberculosis and Air Travel

There is increasing concern among public health agencies and the public about the potential transmission of TB during air travel. The WHO guidelines recommend the tracing and screening of passengers exposed to people with pulmonary TB who sat in adjacent rows for longer than 8 hours and prohibit air travel in patients with pulmonary TB unless the patient has two consecutive negative sputum smears for drug-susceptible TB and two consecutive cultures for MDR-TB.[83] A recent systematic analysis of 13 studies involving TB during air travel found no evidence of transmission in majority of the studies.[84] Only two studies reported reliable evidence of transmission. The analysis suggests that there is a reason to doubt the value of actively screening air passengers for pulmonary TB. The resources that would be spent in such screening could be used for addressing other priorities in TB control.

PREVENTION OF NOSOCOMIAL TRANSMISSION OF MDR-TB

Numerous nosocomial outbreaks of TB have been reported and have often involved MDR strains of *Mycobacterium tuberculosis*.[85,86] In the outbreak in KwaZulu-Natal, South Africa, 85% of cases had a similar genotypic strain denoting nosocomial transmission of resistant TB strains. Table 48.11 lists the characteristics in a TB patient that increases the risk of infectiousness.

The CDC, Atlanta in 1990 made recommendations to try to prevent such nosocomial transmission.[87] These include isolation in a single room with negative pressure relative to the outside, with six air exchanges per hour,

TABLE 48.11: Characteristics in a TB patient that increases the risk of infectiousness

- Presence of cough
- Cavitation on chest radiograph
- Positive Acid-fast Bacilli (AFB) sputum smear result
- TB of the larynx (substantially infectious)
- Failure to cover the mouth and nose when coughing
- Incorrect, lack of or short duration of antituberculosis treatment
- Undergoing cough-inducing or aerosol-generating procedures (e.g. bronchoscopy, sputum induction and administration of aerosolized medications).

the room to be exhausted to the outside; consideration of ultraviolet lamps or particulate filters to supplement ventilation; use of disposable particulate respirators for persons entering the room and during cough inducing procedures. The CDC then published a draft guideline[88] proposing new measures to prevent nosocomial TB, including the use of respirators with high-efficiency particulate air filters (HEPA respirators) in isolation rooms for patients with possible tuberculosis.

Airborne Infection Isolation (AII) Room

Patients with suspected or confirmed TB disease should be placed in airborne infection isolation (AII) room, if available or in a separate room with the door closed, apart from other patients and not in an open waiting area. AII rooms should be single-patient in which environmental factors and entry of visitors and Health Care Workers (HCWs) are controlled to minimize the transmission of *M. tuberculosis*. All HCWs who enter an AII room should wear at least an N-95 disposable respirator. Visitors may be offered respiratory protection (i.e. N-95) and should be instructed by HCWs on the use of the respirator before entering an AII room. AII rooms have specific requirements for controlled ventilation, negative pressure and air filtration. Each inpatient AII room should have a private bathroom. AII rooms in existing healthcare settings should have an airflow of ≥6 air exchanges per hour. In future, new construction or renovation of health care settings should be designed so that AII rooms achieve an airflow of ≥12 air exchanges per hour.

High-Efficiency Particulate Air (HEPA) Filters

HEPA filters can remove at least 99.97% of airborne particles, 0.3 µm in diameter. Particles of this size are most difficult to filter and are thus considered the Most Penetrating Particle Size (MPPS). HEPA filters should be used; (1) when discharging air from local exhaust ventilation booths or enclosures directly into the surrounding room or area; and (2) when discharging air from an AII room (or other negative-pressure room) into the general ventilation system.

While AII rooms and HEPA filters are recommended by the CDC for preventing nosocomial spread of *M. tuberculosis*, it is questionable whether these recommendations could be adapted to our setting due to logistic and financial constraints.

Prophylaxis of MDR-TB Contacts

For contacts thought to be infected with *M. tuberculosis* that is resistant to both isoniazid and rifampicin, no satisfactory chemoprophylaxis is available.[89] There is no consensus regarding the choice of the drugs and the duration of treatment. The CDC has put forth guidelines for the management of persons exposed to MDR-TB.[90] The two suggested regimens for MDR-TB preventive therapy are as follows:

1. Pyrazinamide (25 to 30 mg/kg daily) plus ethambutol (15 to 25 mg/kg daily); or
2. Pyrazinamide (25 to 30 mg/kg daily) plus a quinolone with anti-TB activity (e.g. levofloxacin or ofloxacin). The recommended duration of therapy is 12 months for the patients with underlying immunosuppression and at least 6 months for all other patients. All patients should be closely observed for at least 2 years and a low threshold for referral to a center with experience in managing MDR-TB should be maintained. However, the WHO does not recommend chemoprophylaxis for contacts of MDR-TB due to uncertain efficacy and possibility of aggravating further drug resistance.

FINANCIAL BURDEN OF MDR-TB

The annual financial burden of TB to our country is at least US $ 3 billion (i.e. more than Rs 13,000 crore).[91] The use of second-line drugs on a large programmatic scale will further impose a heavy financial burden. The cost is also increased by the need for improved laboratory capabilities, rigorous follow-up and monitoring of adverse events. This huge challenge was addressed by the WHO in 2000, when the Green light committee (GLC) was formed to successfully negotiate prices of drugs with manufacturers and provide quality assured second-line drugs at concessionary prices to financially burdened countries. In 2002, the GLC was adopted by the newly established Global Fund to Fight Acquired Immunodeficiency Syndrome (AIDS), Tuberculosis and

TABLE 48.12: Cost of treatment with second-line drugs

Type of DR-TB (Resistance to)	*Regimen*	*Estimate using the lowest prices*[#]	*Estimate using the highest prices*[#]
MDR-TB (HRS)	3KEtZOE/18EtOE 3CaEtZOE/18EtOE	20,863.00 32,387.00	77,277.00 88,674.00
MDR-TB (HRSE)	3KEtZOCy/18EtOCy 3CaEtZOCy/18EtOCy	26,533.00 38,057.00	1,70,643.00 1,82,040.00
MDR-TB	6KOEtCyZE/18OEtCsE*	1,30,860.00	2,73,060.00

Ca = capreomycin; Cy = cycloserine; E = ethambutol; Et = ethionamide; K = kanamycin; O = ofloxacin; Z = pyrazinamide

Malaria (GFATM) and today it is the leading financial mechanism supporting the management of MDR-TB in resource-constrained settings. While the standard short-course chemotherapy with isoniazid, rifampicin, pyrazinamide and ethambutol may cost Rs 1900/-, the cost of treatment with second-line drugs works out to be several times more (Table 48.12).

There is no data from India on the feasibility and cost-effectiveness of using second-line drugs to treat patients with drug-resistant TB. A feasibility and cost-benefit analysis was conducted as a part of the national program to treat chronic TB in Peru in 1997.[92] The regimen used was a directly observed standardized 18-month daily regimen, consisting of kanamycin (3 months only), ciprofloxacin, ethionamide, pyrazinamide and ethambutol. The program resulted in a cost of US $ 06 million per year, i.e. 8% of the national tuberculosis program budget and US $ 2381 per patient for those who completed treatment. In the highest cost scenario, in which individualized treatment was assumed to cost US $ 1,00,00 per patient, total annual costs were between US $ 13 million and US $ 20 million and around one-quarter to one-third of the national tuberculosis program budget. Thus, standardized regimes are relatively much cheaper compared to individualized regimes albeit at a price of lower efficacy.

CURE RATES IN MDR-TB AND XDR-TB

Treatment of drug-sensitive TB with traditional first-line agents is associated with excellent cure rates. Short course chemotherapy has been shown to cure 94 to 97% of patients with resistance to streptomycin, isoniazid or to both drugs.[93] On the contrary, the outcome of treatment of MDR-TB with short-course chemotherapy is extremely poor. Studies conducted at TRC, Chennai, had shown that 35 out of 38 patients with MDR-TB failed to respond to conventional regimens.[94] Table 48.13 shows the cure rates achieved in various studies on MDR-TB and XDR-TB.[95]

CONCLUSION

The global TB epidemic has been complicated by the emergence of multidrug and extensively drug-resistant strains of TB. Indiscriminate use of second-line drugs for treating MDR-TB has already given rise to the development of XDR-TB and if this practice goes uncurbed, it may soon emerge as the dominant TB strain throughout the world. Since drug resistance is a man-made phenomenon, every effort should be made to diagnose and treat drug-sensitive TB effectively at the grassroot level and prevent the development of drug resistance. MDR-TB and XDR-TB are pure laboratory diagnoses and therefore, require quality laboratory support for timely and accurate diagnosis. The treatment of MDR-TB is lengthy and costly and requires excellent patient compliance for prolonged periods for achieving acceptable cure rates. Studies in the recent past have shown that MDR-TB and even XDR-TB can be treated effectively with the currently available drugs and achieve a satisfactory outcome. Control of drug-resistant TB requires a strong health infrastructure to ensure delivery of effective therapy coupled with surveillance and monitoring activities, to enable timely intervention to limit transmission and spread of the disease.

TABLE 48.13: Treatment outcome in MDR-TB and XDR-TB

Study, year of publication	*Type of DR-TB*	*Treatment outcome*
Goble et al, 1993	MDR-TB [n = 171]	Cured = 65% Treatment failure = 35%
Sharma et al, 1996	MDR-TB [n = 19]	Sputum smear conversion = 18/19 (94.7%)
Park et al, 1998	MDR-TB [n = 107]	Cured = 82.5% Treatment failure = 17.5%
Yew et al, 2000	MDR-TB [n = 63]	Cured = 81% Treatment failure = 14.3%
Kim et al, 2001	MDR-TB [n = 1011]	Cured = 48% Treatment failure = 8.1% Default = 39%
Tahaoglu et al, 2001	MDR-TB [n = 158]	Cured or completed treatment = 77% Treatment failure = 8%
Mitnick et al, 2003	MDR-TB [n = 75]	Cured = 83% Death = 8%
Nathanson et al, 2006	MDR-TB [n = 1047]	Cured or completed treatment = 69.7% Treatment failure = 6.7%
Gandhi et al, 2006	XDR-TB [n = 53]	Death = 52/53 (98.1%) HIV positive = 44/44 tested
Sharma, 2007	MDR-TB [n = 172] XDR-TB [n = 1]	Cured = 41.6% Treatment failure = 38.7%
Dhingra et al, 2008	MDR-TB [n = 27]	Cured = 48% Default = 37%
Shean et al, 2008	MDR-TB [n = 491]	Cured or completed treatment = 49% Treatment failure = 5% Default = 29%
Masjedi et al, 2008	MDR-TB [n = 43]	Cured/completed treatment = 67.5% Death = 18.6%
Mitnick et al, 2008	XDR-TB [n = 48] MDR-TB [n = 603]	Cured or completed treatment = 60.4% of XDR-TB; Treatment failure = 10.4% of XDR-TB;Cured or completed treatment = 66.3% of MDR-TB; Treatment failure = 2.1% of MDR-TB
Bonilla et al, 2008	XDR-TB [n = 43]	Cured or completed treatment = 49% Death = 19%
Kwon et al, 2008	XDR-TB [n = 27] MDR-TB [n = 128]	Cured or completed treatment = 65% of XDR-TB Cured or completed treatment = 66% of MDR-TB Treatment failure = 14% overall
Banerjee et al, 2008	XDR-TB [n = 18] MDR-TB [n = 406]	Completed treatment = 41.2% XDR-TB Death = 29.4% XDR-TB
Keshavjee at al, 2008	XDR-TB [n = 29] MDR-TB [n = 579]	Cured or completed treatment = 48.3% of XDR-TB; Treatment failure = 31% of XDR-TB; Cured or completed treatment = 66.7% of MDR-TB; Treatment failure = 8.5% of MDR-TB

Revised National Tuberculosis Control Programme in India—DOTS and DOTS Plus*

D Behera

INTRODUCTION

Tuberculosis

Tuberculosis (TB) is an infectious disease caused by *Mycobacterium tuberculosis*, and rarely by other organisms of the "tuberculosis complex".

Tuberculosis is most commonly transmitted by inhalation of infected droplet nuclei, which are discharged in the air when a patient with untreated sputum-positive TB coughs or sneezes. If the bacillus succeeds in infecting a person, only about 5 to 10% of such infected persons (primary infection) develop active disease. In the remaining 90 to 95% of infected persons, initial infection usually goes unnoticed. Tuberculin sensitivity appears within a few weeks of infection and initial lesions commonly heal leaving no residual changes except occasional pulmonary or tracheobronchial lymph node calcifications (primary complex). Infection occurs almost exclusively through the respiratory route. The infection may then spread from the primary lung lesion to any part of the body via the blood stream, lymphatic and bronchial systems.

Postprimary TB (active TB disease) arises from endogenous reactivation of latent foci, which remained dormant since the initial infection or exogenous reinfection. Postprimary TB usually affects the lungs (more than 85%), but can involve any part of the body. Pulmonary TB which is sputum smear-positive is highly infectious and should receive topmost priority for treatment. Cases which are smear-negative are much less infectious than those, which are smear-positive. Extrapulmonary TB can affect the lymph nodes, pleura, bones and joints, the genitourinary tract, the nervous system (meningitis), intestines, etc. The precise diagnosis of some of the severe forms is a challenge to physicians as they present a symptom complex with extraordinary diversity. However, patients with extrapulmonary TB (without concomitant pulmonary TB) hardly ever spread the disease to others. If untreated, TB leads to death within two to three years in at least half the patients. About 20 to 25% have natural healing and 25 to 30% remain positive and continue to spread the disease in the community.

Extent of the Tuberculosis Problem

One-third of the global population is estimated to be infected with TB bacillus. The annual incidence of new cases of all forms of TB (pulmonary and extrapulmonary) worldwide is estimated to be approximately 8.8 million, of which about 95% occur in developing countries. Globally, it is estimated that 1.8 million people die from TB each year—the majority of them in developing countries.

Tuberculosis remains a major public health problem in India. About 40% of the population in India is estimated to be infected with TB bacillus. Every year approximately 1.8 million people develop TB and nearly 400,000 die from it. The annual incidence of smear-positive TB is estimated to be 75 per 100,000 population [based on Annual Risk of Tuberculous Infection (ARTI) study done for the four zones of the country from 2000 to 2003] India accounts for one-fifth of global incidence of TB and tops the list of 22 high TB burden countries.

TB kills more adults in India than any other infectious disease.

---

*SK Jindal, R Agarwal. Oxygen Therapy. In: D Behera (Ed.) Revised National Tuberculosis Control Programme in India—Dots and Dots Plus, 2nd edition. New Delhi: Jaypee Brothers Medical Publishers; 2008. pp. 585-623.

In India, everyday:

- More than 5,000 develop TB disease
- More than 1,000 people die of TB (i.e. 1 death every 1.5 minutes).

Tuberculosis is a barrier to socioeconomic development. It is estimated that the annual cost to society and the country due to TB amounts to nearly US$ 3 billion in indirect costs and US$ 300 million in direct costs. The greatest burden of tuberculosis incidence and mortality in India is in adults aged 15 to 60 years, which include the most productive members of society. TB affects more men than women, but still kills more women than all causes of maternal mortality put together.

Every Year due to TB (As per Estimates Made in 1997)

- More than 170 million work-days are lost
- Nearly 300,000 school children dropout from the schools
- More than 100,000 women are rejected by their families.

The Human Immunodeficiency Virus (HIV) epidemic has the potential to worsen the TB situation, increasing the number of TB cases and accelerating the progression of TB infection to active disease. It is estimated that 50 to 60% of HIV-infected people will develop TB disease in their lifetime when compared to 10% of HIV-negative persons infected with TB.

Another challenge to TB control in India is MDR-TB. Fortunately the data available to date shows that the levels of MDR-TB remain relatively low, at around 3%, amongst new patients and 12% in retreatment cases. However, these relatively low percentage figures translate into large absolute number of MDR-TB cases, who can transmit their drug resistant disease to others and require effective treatment.

Childhood TB is a reflection of the prevalence of sputum smear-positive Pulmonary Tuberculosis (PTB) and the extent of transmission of TB infection in the community. The incidence of TB in children is less compared to adults, but they are likely to suffer from more serious forms of TB and may die if not treated properly.

TB Control in India

The National Tuberculosis Programme of India (NTP) was initiated in 1962, based on the research by Tuberculosis Research Centre, Chennai and National TB Institute, Bengaluru. The national program was designed for domiciliary treatment using self-administered standard drug regimens. A large network of District TB centers were created with trained staff and infrastructure. Despite the existence of the NTP, there was little impact on the TB burden till 1992. A combined review of the program in 1992 concluded that the NTP could not achieve the objectives because of low priority, managerial weaknesses, over dependence on X-rays for diagnosis and inadequate funding. Incomplete treatment was the norm rather than exception due to the low rates of treatment adherence and lack of supervision.

On the recommendations of an expert committee, a revised strategy to control TB was pilot-tested in 1993 in a population of 2.35 million and thereafter increased in phased manner. A full-fledged program was started in 1997 and rapidly expanded with excellent results. This Revised National Tuberculosis Control Programme (RNTCP) uses the Directly Observed Treatment Short-Course (DOTS) chemotherapy strategy, which is based on results of tuberculosis research done in India. By June 2005, the RNTCP had covered more than 1 billion population (more than 90% of the country was covered) and whole of the country was expected to be covered by 2005 end. Since the inception of RNTCP and up to June 2005, more than 4.5 million patients were initiated on treatment and about 750,000 additional lives were saved.

REVISED NATIONAL TUBERCULOSIS CONTROL PROGRAMME

Objectives of the RNTCP

The Goal of the RNTCP is to decrease mortality and morbidity due to TB and reduce the transmission of infection until TB ceases to be a major public health problem. The goal is achieved through the following objectives. The Objectives of the RNTCP are:

1. To achieve and maintain a cure rate of at least 85% among newly detected infectious (new smear-positive) cases.
2. To achieve and maintain detection of at least 70% of such cases in the population.

Effort should be made to first achieve the objective 1 and then make additional efforts to meet the objective 2.

TB can be controlled by early detection and effective treatment of infectious pulmonary TB cases who act as the sources of infection. Thus the basic curative as well as preventive strategy is the treatment of infectious TB patients until cure. The priority for treatment are newly diagnosed, sputum-positive pulmonary tuberculosis cases, as they are the main sources of infection and are more likely to die unless effectively treated.

The RNTCP is based on the DOTS strategy, which is the internationally recommended strategy of choice for

TB control. The DOTS strategy has the following five components:

- **Sustained political commitment** to increase human and financial resources and make TB control a nation-wide activity integral to national health system.
- **Access to quality-assured TB sputum microscopy** for case detection among persons presenting with, or found through screening to have, symptoms of TB (most importantly prolonged cough).
- **Standardized short-course chemotherapy** to all cases of TB under proper case management conditions, including direct observation of treatment—proper case management conditions imply technically sound and socially supportive treatment services.
- **Uninterrupted supply of quality-assured drugs** with reliable drug procurement and distribution systems.
- **Recording and reporting system enabling outcome assessment** of each and every patient and assessment of the overall program performance.

Directly Observed Treatment, in which a trained peripheral health worker or community volunteer watches as patients swallow all medicines, is fundamental to ensuring cure. DOT should be ensured for every dose in the intensive phase of treatment and at least the first dose of the week in the continuation phase. DOT is one of the five components of the DOTS strategy.

The diagnosis and treatment of TB are functions of the general health services and hence a part and parcel of Primary Health Care. At the District Level, the District Tuberculosis Centre (DTC) acts as the nodal center for planning, training, logistics, quality control, monitoring and supervision.

Early detection of disease should be done in all symptomatic patients reporting to the general health services with cough of duration of three weeks or more by the examination of three sputum smears for AFB. Contacts of smear-positive cases should also be evaluated. Sputum examination and treatment of TB, including anti-TB drugs are provided free of charge under the program. The outcome of treatment is evaluated by the analysis of the results of quarterly cohorts of all registered cases.

Organizational Structure and Functions

The structure of RNTCP comprises of five levels: National level, state level, district level, subdistrict level and peripheral health institution level.

National Level

At the central level the Revised National TB Control Programme is managed by Central TB Division of Directorate General Health Services, the technical arm of the Ministry of Health and Family Welfare (MoHFW). A National Programme Manager, Deputy Director General TB (DDG TB), is in charge of the tuberculosis program for the entire country. The Joint Secretary from the administrative arm of the MoHFW looks after the financial and administrative control of the program. The Central TB Division (CTD) is assisted by three national tuberculosis institutes, namely, National Tuberculosis Institute (NTI), Bengaluru; Tuberculosis Research Centre (TRC), Chennai; and Lala Ram Sarup (LRS) Institute of Tuberculosis and Respiratory Diseases, New Delhi.

Organizational structure at central level is shown in Flow chart 49.1.

Central TB Division has five units to manage various program activities. These units are headed by the Chief Medical Officer (CMO) of the rank of Deputy Program Manager (DPM) and assisted by other technical and secretarial staff. The five units are as mentioned below:

1. Supervision, monitoring and epidemiological surveillance unit
2. Human resource development unit
3. Procurement, supply and logistic unit
4. Finance unit
5. Advocacy and IEC unit.

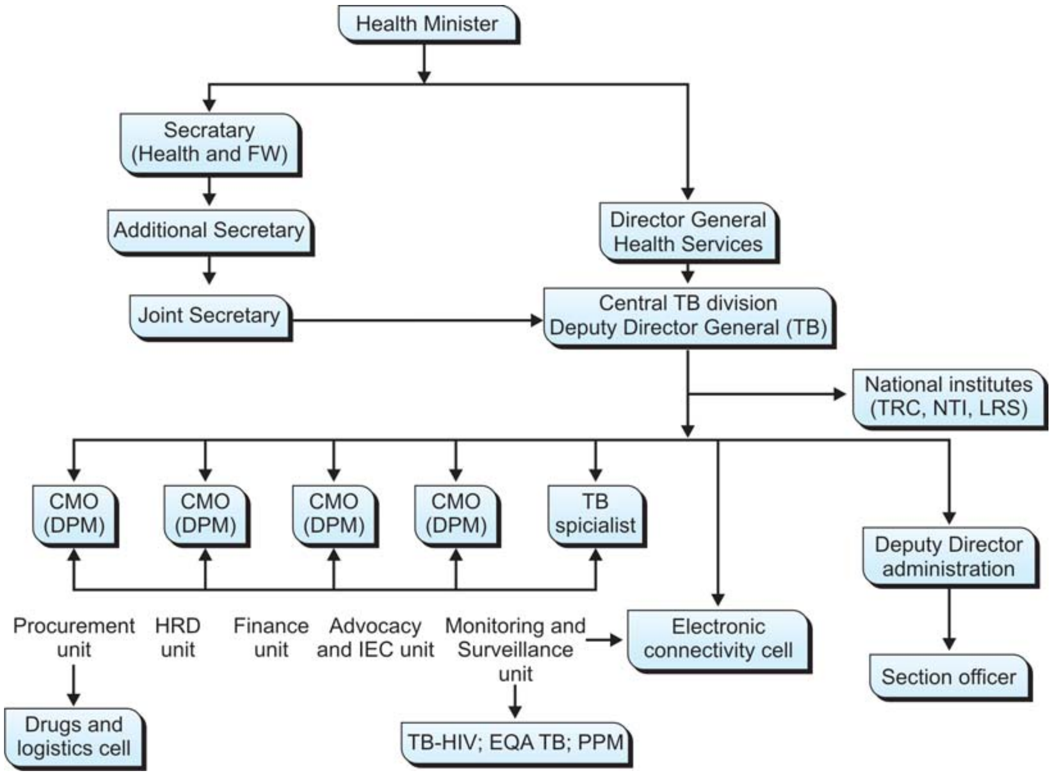
State Level

At the State level, the State Tuberculosis Officer (STO) is responsible for planning, training, supervising and monitoring the program in their respective states as per the guidelines of the State TB Control Society or its equivalent (STCS or its equivalent). The STO based at the State TB Cell is administratively answerable to the State Government and technically follows the instructions of the CTD, and coordinates with CTD and the districts for executing the duties mentioned above. There should be a full-time STO trained in RNTCP for each state.

With the rapid expansion of the program, MoHFW has restructured and strengthened the functions of the STCS or its equivalent. The States have increased ownership and accountability for implementation. Capacity building and decentralization are taking place in the technical, financial as well as logistic aspects of the program. The States, via the STCS or its equivalent, are now directly responsible for monitoring and supervising the work of District TB Control Societies (DTCS) or its equivalent.

Structure of RNTCP at the state level is shown in Flow chart 49.2.

Flow chart 49.1: Organizational structure: Central level



Health Minister
Secratary (Health and FW)
Additional Secretary
Joint Secretary
Director General Health Services
Central TB division Deputy Director General (TB)

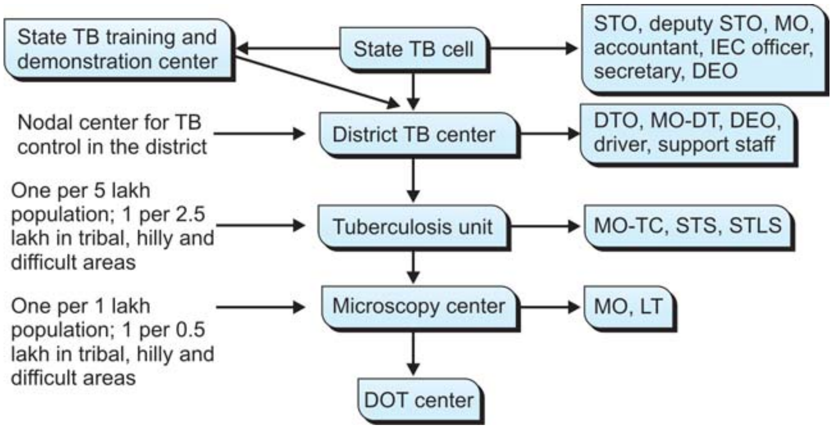
CMO (DPM)
CMO (DPM)
CMO (DPM)
CMO (DPM)
TB spicialist
Deputy Director administration
Procurement unit
HRD unit
Finance unit
Advocacy and IEC unit
Monitoring and Surveillance unit
Electronic connectivity cell
Section officer
Drugs and logistics cell
TB-HIV; EQA TB; PPM

Flow chart 49.2: Structure of RNTCP at the state level



State TB training and demonstration center
State TB cell
STO, deputy STO, MO, accountant, IEC officer, secretary, DEO
Nodal center for TB control in the district
District TB center
DTO, MO-DT, DEO, driver, support staff
One per 5 lakh population; 1 per 2.5 lakh in tribal, hilly and difficult areas
Tuberculosis unit
MO-TC, STS, STLS
One per 1 lakh population; 1 per 0.5 lakh in tribal, hilly and difficult areas
Microscopy center
MO, LT
DOT center

Functions of the State TB Cell

In major states of the country, a State TB Training and Demonstration Centre (STDC) supports the State TB cell. The STDC has three units—a training unit, supervision and monitoring unit and an IRL supporting an effective Quality Assurance system of the RNTCP Sputum smear microscopy network in the State.

Functions of the STDC

The **State TB Cells** have been provided with equipment, infrastructure and contractual staff to carry out its activities. The staff at the STC includes the State TB Officer, Deputy State TB Officer, Medical Officer STC, State IEC Officer, State Accountant, Secretarial Assistant, Pharmacist and Data Entry Operator.

State Drug Stores (SDS) for anti-TB drugs are essential for the effective management of drugs logistics. For the long-term sustainability of the program, decentralization of many aspects of drug management to the states has been done. One SDS (@ 1 per 50 million population) is established in all major states and in those states where management of drug logistics is difficult, e.g. hilly areas, difficult to access areas and areas prone to natural calamities.

District Level

The district is the key level for the management of primary health care services. The district level (or municipal corporation level) performs functions similar to those of the state level in its respective area. The Chief District Health Officer (CDHO)/Chief District Medical Officer (CDMO) or an equivalent functionary in the district is responsible for all medical and public health activities, including control of TB. The District Tuberculosis Centre (DTC) is the nodal point for TB control activities in the district. In RNTCP, the primary role of the DTC has shifted from a clinical one to a managerial one. The District TB Officer (DTO) at the DTC has the overall responsibility of management of RNTCP at the district level as per the program guidelines. The DTO is also responsible for involvement of other sectors in RNTCP and is assisted by an MO, Statistical Assistant and other paramedical staff. For each district, there should be a full-time DTO, who is trained in RNTCP at a central level institution.

Subdistrict Level (Tuberculosis Unit Level)

A major organizational change in RNTCP is the creation of a subdistrict level (Tuberculosis Unit). The Tuberculosis Unit (TU) will consist of a designated Medical Officer-Tuberculosis Control (MO-TC) who does tuberculosis work in addition to his/her other responsibilities, as well as two full-time supervisory staff for tuberculosis work—a Senior Treatment Supervisor (STS) and a Senior Tuberculosis Laboratory Supervisor (STLS). TUs are generally based in a Community Health Centre (CHC), Taluk Hospital (TH) or Block Primary Health Centre (BPHC). The team of STS and STLS at the Tuberculosis Unit Level (TU level) are under the administrative supervision of the DTO/MO-TC. The TU covers a population of approximately 5,00,000 (2,50,000 in tribal, desert, remote and hilly regions). The TU will have one Microscopy Centre for every 100,000 population (50,000 in tribal, desert, remote and hilly regions) referred to as the Designated Microscopy Center (DMC). DMCs are also provided in medical colleges, corporate hospitals, ESI, railways, Nongovernmental Organizations (NGOs), private hospitals, etc. depending upon requirements. The TU is responsible for the accurate maintenance of the Tuberculosis Register and timely submission of quarterly reports to the district level. The TU is the nodal point for TB control activities in the subdistrict.

MO-TC at the TU has the overall responsibility of management of RNTCP at the subdistrict level and is assisted by the STS and STLS. The MO-TC is trained in RNTCP at a state level institution, preferably State TB Training and Demonstration Centre (STDC).

MO-TC is expected to undertake supervisory visits in the TU for seven days in a month.

Health Institutions (PHIs)

For the purpose of RNTCP, a PHI is a health facility, which is manned by at least a medical officer (even if the post is currently vacant). At this level are the dispensaries, PHCs, CHCs, referral hospitals, major hospitals, specialty clinics/hospitals (including other health facilities)/TB hospitals/Medical colleges within the district. All health facilities in the private/NGO sector participating in RNTCP are also considered as PHIs under the program. Some of these PHIs will also be DMCs. All PHIs with/without DMCs should submit a monthly PHI level report to the respective TUs and the district.

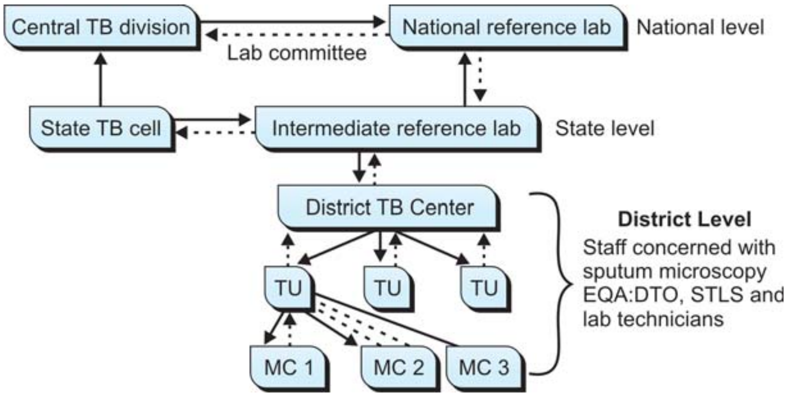
Case-finding and treatment of TB are integrated into the functions of the medical staff of government health services. The staff in specialized services, which support the program (DTC), has these functions in addition to supporting the DTO in the management of the program. In situations where more than one MO is posted in any of the peripheral health centers, one of them may be identified and entrusted with the responsibilities of the RNTCP.

TB Laboratory Services

The aims of the laboratory service are: (i) the diagnosis of cases, and (ii) monitoring of treatment.

The laboratory network for RNTCP in India consists of three designated National Reference Laboratories (NRLs) namely Tuberculosis Research Centre, Chennai; National Tuberculosis Institute, Bengaluru; and LRS Institute of Tuberculosis and Respiratory Diseases, Delhi (JALMA, Agra is the 4th NRL at present) about 24 IRLs at state level; and about 10,000 Microscopy Centers or peripheral laboratories. A nodal laboratory in each state will be designated as IRL. Usually the STDCs (State TB

Flow chart 49.3: Structure of RNTCP laboratory network



Training and Demonstration Centres) would be designated as IRL provided that they have a well functioning laboratory. Else, the state is to identify a Public Health Laboratory or Medical College Laboratory and designate that as the IRL after the laboratory is assessed by a visit from the NRL. The RNTCP microscopy centers in each district are the peripheral laboratories.

A Central Laboratory Committee has been constituted with the microbiologists of the three NRLs and CTD representatives as members. This committee works as a task force to guide laboratory-related activities of the program.

Structure of RNTCP Laboratory Network is shown in Flow chart 49.3.

The different levels of laboratories under RNTCP are as follows:

National Reference Laboratory: Each NRL will supervise sputum microscopy EQA of 8 to 11 states designated under them. The NRLs are internationally accredited laboratories as their EQA is being performed by a WHO reference laboratory for antituberculous drug susceptibility testing.

Intermediate Reference Laboratory: The states will designate one Intermediate Reference Laboratories in the STDC or medical college or in any Public Health Laboratory of the state. The IRL should be a facility deemed fit for accreditation by the respective NRL looking after the state. The designated IRL will conduct sputum microscopy EQA for the state and occasionally for a neighboring state or union territory based on an understanding between the two concerned STCSs or its equivalent/ CTD. The IRL will ensure proficiency of RNTCP staff for carrying out good quality diagnosis by providing technical training to district and sub-district technicians and STLS.

Designated Microscopy Center: Sputum microscopy diagnostic services under RNTCP are provided by Designated Microscopy Centers (DMC) established for every one lakh population (50,000 population in tribal and hilly areas). In addition the DMCs are also established at medical colleges, corporate hospitals, ESI, railways, NGOs, large private hospitals and other major hospitals.

The DMCs should satisfy the following criteria:

1. RNTCP-trained laboratory technician should be present.
2. Binocular microscope should be present in the laboratory.
3. Physical infrastructure in laboratory should meet RNTCP guidelines.
4. Daily new adult OPD of at least 60–100 and/or workload of at least three to five sputum smears per day for the laboratory technician in the laboratory.

DMCs in the public sector, at the onset of the program, were provided with funds to undertake minor civil works to build up their physical infrastructure and were provided with binocular microscopes.

In addition, before designating a DMC in other sectors, there should be a formal agreement by the hospital/laboratory to take part in the external quality assurance and to allow the concerned RNTCP staff for supervision as per RNTCP guidelines.

If the above criteria are met by any private laboratory, it can be considered for establishing as a DMC. However, the population norms for DMCs (one DMC per 100,000 population in the usual cases and 50,000 population in remote and difficult areas) should not prevent from designating a private hospital/laboratory as DMC if the decision is based on program needs and fulfillment of the above criteria.

Any laboratory/private health facility not fulfilling the above criteria may be considered for referral/ sputum collection center.

There is no provision from RNTCP for civil works, binocular microscope and LT for laboratories in private and NGO sectors. For such DMCs, the logistics, including laboratory consumables, registers and forms may be supplied from RNTCP as per guidelines. In exceptional cases provision of BMs may be considered for DMCs in other sectors by CTD.

Sputum Collection Centers

To improve access to diagnostic services in areas, such as the tribal, hilly, difficult to reach areas of the country sputum collection centers may be established. Collection and transport of sputum samples should be as per the RNTCP guidelines (refer section on "Diagnosis of Pulmonary Tuberculosis"). Each district shall identify such areas and plan for establishment of the sputum collection centers.

Private practitioners in urban and rural areas can also collect sputum samples and send to the nearest DMC as per PP scheme 1 (Refer guidelines on "Involvement of Private practitioners in RNTCP").

DIAGNOSIS OF PULMONARY TUBERCULOSIS

Tuberculosis affects the lungs in more than 85% of cases. This form of the disease is called pulmonary tuberculosis. Pulmonary tuberculosis is an infectious disease and spreads mainly by droplet infection. Sputum-positive pulmonary TB patients are the main source of infection. It is estimated that an untreated smear-positive pulmonary TB patient infects 10 to 15 persons annually. Therefore, it is very important to identify TB suspects and diagnose them early in order to effectively treat and make them noninfectious.

Identification of Tuberculosis Suspects

Most patients with TB visit health facilities promptly after symptoms occur. Hence, every adult patient with respiratory symptoms attending the health facility must be asked about symptoms suggestive of tuberculosis.

The most common symptom of pulmonary TB is a persistent cough for 3 weeks or more, usually with expectoration. It may be accompanied by one or more of the following symptoms, such as weight loss, chest pain, tiredness, shortness of breath, fever, particularly with rise of temperature in the evening, in some cases there will be blood in the sputum, loss of appetite and night sweats.

About 2 to 3% of new adult outpatients in a general health facility are expected to have cough for three weeks or more and on an average 10% of the suspects are expected to have sputum-positive pulmonary TB.

Case Finding Tools

The main tools for diagnosing pulmonary TB are sputum smear microscopy, chest X-ray, and culture of *M. tuberculosis* bacilli.

- *Sputum smear microscopy:* This is the primary tool for diagnosing TB as it is easy to perform at the peripheral laboratories, not expensive and specific with low inter and intra-reader variation. It is simple and requires minimum training. Can be used for diagnosis, monitoring and defining cure. Therefore, this is the key diagnostic tool used for case detection in RNTCP. If good diagnostic practices are followed, it is expected that at least 50% of the new pulmonary TB patients diagnosed will be smear-positive.
- *Chest X-ray:* X-ray as a diagnostic tool is sensitive, but less specific with large inter- and intra-reader variations. No shadow is typical of TB, 10 to 15% culture-positive cases remain undiagnosed and 40% patients diagnosed as having TB by X-ray alone may not have active TB disease. It is supportive to microscopy.
- *Culture:* Culture of *M. tuberculosis* bacilli is very sensitive and specific, but is expensive as it requires a specialized laboratory set-up and results are available only after several weeks. If available, culture of tubercle bacilli may be helpful, although in sputum-negative cases, a clinical decision to treat for TB based on X-ray findings and lack of response to broad-spectrum antibiotics would be more practical and also ensure prompt treatment. Culture and sensitivity testing is valuable for the diagnosis and management of drug-resistant tuberculosis, besides epidemiological surveillance and planning.
- *Tuberculin test:* Tuberculin test may be useful as an additional tool for diagnosing pediatric TB, in whom a positive test is more likely to reflect recent infection with TB and indicates a much higher risk of developing disease. However, the tuberculin test has no role in diagnosing adult pulmonary TB disease in India.

Case Finding Methods

- Examination of sputum of patients with symptoms suggestive of TB, who present on their own initiative at health facilities
- Promotion of awareness in the community, amongst the medical professionals and all medical staff

regarding respiratory symptoms, notably persistent cough for three weeks or more, and the need to obtain and examine there sputum specimens for the diagnosis of TB

- Examination of household contacts of smear-positive TB patients; irrespective of the duration of cough
- Examination of extrapulmonary TB cases with cough of any duration.

Diagnosis by Sputum Microscopy

A medical practitioner at a health facility screens patients and advises those who are suspected of having TB (cough for three weeks or more) to undergo sputum smear examination at the nearest RNTCP designated microscopy center. A laboratory form for sputum examination has to be filled and sent to the laboratory with the patient. The sputum specimen may be collected and transported to the laboratory if the patient is unable to travel to microscopy center.

Microscopic examination of sputum is, as a rule, the only way by which the diagnosis of pulmonary TB can be confirmed. Whenever TB is suspected, at least three specimens of sputum should be collected over 2 consecutive days and examined by microscopy. Only one laboratory form needs to be filled for all the three specimens of the patient.

Guidelines for Collecting Sputum for Smear Microscopy

- *First visit to the microscopy center:* When a TB suspect reports to the laboratory, a specimen is collected on the spot. She is given a sputum container with the laboratory serial number written on its side and is instructed to inhale deeply two to three times with his/her mouth open, cough out deeply from the chest, open the container, spit out the sputum into it and close the container tightly. This specimen is called a spot specimen. The patient is then given a similarly marked empty sputum container to collect a specimen early next morning and bring it to the laboratory. This specimen is called an early morning specimen.
- *Second visit to the microscopy center:* The early morning specimen brought by the patient is received and a further spot specimen is collected.

  Thus there will be three samples: SPOT-EARLY MORNING-SPOT. (Now two samples are required wef April, 2009)

  Obtaining a good sputum specimen is crucial for quality sputum microscopy. The following steps have to be observed to get good sputum specimen:

- *Tasks performed before sputum collection:* Before a health worker collects a sputum specimen, the reasons for sputum collection have to be explained to the patient. The laboratory technician/health worker must ensure that the patient's full address is entered in the laboratory form.
- *Tasks performed during sputum collection:* A specimen collected under the proper guidance of a health worker is likely to yield more conclusive results than one produced by a patient without any guidance. Sputum should preferably be collected in open air or in a vacant room with open windows. The health worker or the laboratory technician should stand behind the patient. The health worker should also ensure that no one stands in front of the patient. If a patient coughs out only saliva, she should be asked to try again to bring out sputum. Patient must be asked to rinse the mouth before bringing out the sputum samples.
- *Tasks performed after sputum collection:* Sputum specimens should be examined on the same day. In cases where sputum needs to be transported to a DMC, it must be examined within a week after collection. Storage of sputum samples should be in cool place/refrigerator. A smear is made, fixed and stained using the Ziehl-Neelsen staining technique.

If the first spot specimen is positive by microscopy and the patient does not return for the second sputum test, an immediate search must be made to find the patient to prevent the dissemination of infection in the community. In the interest of the patient, second and third specimens of sputum must be collected and examined. To facilitate this, it is important to note down the complete address of all symptomatic patients.

Smear Preparation, Staining and Reading

All specimens should be examined in the nearest designated microscopy center, as a rule, by the Ziehl-Neelsen method.

ZIEHL-NEELSEN STAINING PROCEDURE

1. A new unscratched slide is selected and the slide is labeled with the Laboratory Serial Number with a diamond marking pencil.
2. A smear is made from yellow purulent portion of the sputum using a broom stick. A good smear is spread evenly, 2 cm × 3 cm in size and is neither too thick nor too thin. The optimum thickness of the smear can be assessed by placing the smear on a

printed matter. The print should be readable through the smear. Smear preparation should be done near a flame. This is required, as six inches around the flame is considered as a sterile zone, which coagulates the aerosol raised during smear preparation.

3. The slide is allowed to air dry for 15 to 30 minutes.
4. The slide is fixed by passing it over a flame three to five times for three to four seconds each time.
5. One percent filtered carbol fuchsin is poured to cover the entire slide.
6. The slide is gently heated with carbol fuchsin on it, until vapors rise. Do not boil.
7. Carbol fuchsin is left on the slide for five minutes.
8. The slide is gently rinsed with tap water until all free carbol fuchsin stain is washed away. At this point, the smear on the slide looks red in color.
9. Twenty-five percent sulfuric acid is poured onto the slide and allowed to stand for two to four minutes.
10. The slide is gently rinsed with tap water and tilted to drain off the water.
11. A properly decolorized slide appears light pink in color. If the slide is still red, sulfuric acid is reapplied for one to three minutes and then rinsed gently with tap water.The back of the slide is wiped clean with a swab dipped in sulfuric acid.
12. 0.1% methylene blue is poured onto the slide and left for 30 seconds. Then the slide is rinsed gently with tap water and allowed to dry.
13. The slide is examined under the binocular microscope using ×40 lens to select the suitable area and then examined under ×100 lens using a drop of immersion oil.
14. The results are recorded in the laboratory form and the laboratory register.
15. The slides are inverted on a tissue paper till the immersion oil is completely absorbed. Xylene is not to be used for cleaning the slides, as it may give false results at repeat examination after storage.
16. All positive and negative slides are stored serially in the same slide-box until instructed by the supervisor.
17. All contaminated materials are disinfected as per guidelines before discarding (Refer to section on "Infection Control and Hospital Waste Management").

Sputum smears are examined and interpreted as indicated in Table 49.1.

Classification of Tuberculosis Cases

It is important to classify cases of TB in order to determine the correct combination of drugs and duration of treatment. Classification of pulmonary cases should be based on at least three sputum smear examinations. Sputum should also be examined for the cases of suspected extrapulmonary TB, if pulmonary symptoms are present.

Pulmonary Tuberculosis

a. *Smear-positive patient*: A patient with at least two initial sputum smear examinations (direct smear microscopy) positive for Acid-fast Bacilli (AFB);
   Or: A patient with one sputum examination positive for AFB and radiographic abnormalities consistent with active pulmonary TB as determined by the treating MO;
   Or: A patient with one sputum specimen positive for AFB and culture positive for *M. tuberculosis.*
b. *Smear-negative patient*: A patient having symptoms suggestive of TB with at least three sputum examinations negative for AFB, and radiographic abnormalities consistent with active pulmonary TB as determined by the treating MO, followed by a decision to treat the patient with a full course of anti-TB therapy;
   Or: A patient whose diagnosis is based on culture positive for *M. tuberculosis*, but sputum smear examinations negative for AFB.

TABLE 49.1: Ways to examine and interpret sputum smear

Examination finding	*Result as recorded*	*Grading*	*No. of fields examined*
> 10 AFB per oil immersion field	Positive	3+	20
1–10 AFB per oil immersion field	Positive	2+	50
10–99 AFB per 100 oil immersion fields	Positive	1+	100
1–9 AFB per 100 oil immersion fields	Positive	Scanty*	100
No AFB in 100 oil immersion fields	Negative	Negative	100

*Record exact number seen in 100 fields

Extrapulmonary Tuberculosis

Extrapulmonary Tuberculosis (EPTB) is tuberculosis of organs other than the lungs, such as the pleura (pleurisy), lymph nodes, intestines, genitourinary tract, skin, joints and bones, meninges of the brain, etc.

Diagnosis should be based on one culture-positive specimen from an extrapulmonary site, or histological or radiological, or strong clinical evidence consistent with active extrapulmonary TB followed by the treating MO's decision to treat with a full course of anti-TB therapy.

Pleurisy is classified as extrapulmonary TB: A patient diagnosed with both sputum smear-positive pulmonary TB and extrapulmonary TB should be classified as a case of pulmonary TB.

Diagnostic Algorithm of RNTCP

Patients with at least two positive smear results are diagnosed by the physician as a case of smear-positive TB. They are further classified as new or old cases based on their treatment history, and appropriate therapy is prescribed.

For patients with only one sputum-positive result on smear examination, chest X-ray is taken. If findings of the X-ray are consistent with pulmonary tuberculosis, patient is diagnosed by the physician as a case of sputum-positive pulmonary TB.

Patients in whom all three samples are negative on sputum smear examination are prescribed symptomatic treatment and broad-spectrum antibiotics (such as co-trimoxazole, doxycycline, amoxicillin) for 10 to 14 days. In such cases antibiotics such as fluoroquinolones (ciprofloxacin, ofloxacin, etc.), rifampicin or streptomycin, which are active against tuberculosis, are not to be used. Most patients are likely to improve with antibiotics if they are not suffering from TB. If the symptoms persist after a course of broad-spectrum antibiotics, repeat sputum smear examination (three samples) must be done for such patients.

If two or more smears are positive, the patient is diagnosed as having smear-positive pulmonary TB. If only one sputum sample is positive, chest X-ray is taken. If findings of the X-ray are consistent with pulmonary tuberculosis, patient is diagnosed by the physician as a case of sputum-positive pulmonary TB.

If the results for all the three sputum samples of repeat examination are found negative then a chest X-ray is taken. If findings of the X-ray are consistent with pulmonary tuberculosis, patient is diagnosed by the physician as a case of sputum-negative pulmonary TB.

Patients with EPTB who also have cough of any duration, should have three sputum samples examined. If the smear result is positive, the patient is classified as pulmonary TB and his/her treatment regimen will be that of a case of smear-positive pulmonary TB.

When the referring medical practitioner receives the results of sputum examination, and it is decided to put the patient on chemotherapy, patient must be counseled and motivated to adhere to treatment as recommended. The patient is told about TB, mode of transmission, precautions to be taken to prevent the spread, importance of directly observed treatment and its duration, and the need for prompt evaluation of children under six years or household contacts with cough of any duration. The patient should also be informed that his/her address would be verified by a competent person prior to the start of treatment.

Follow-up Smear Examination

During follow-up two sputum samples are to be tested each time. The schedule is as follows:

- For smear-positive TB patients, two sputum samples (Morning-Spot) have to be tested each time on three occasions—(i) At the end of the intensive phase (two months for new cases and three months for retreatment cases), (ii) Two months into the continuation phase (at the end of four months for new cases/five months for retreatment cases) and (iii) At the end of treatment. If the smear is positive at the end of the intensive phase, it should be tested again at the end of extended IP (three months in new cases and at four months in retreatment cases).
- For smear-negative patients, two sputum samples have to be tested on two occasions–at the end of IP and at the end of treatment.

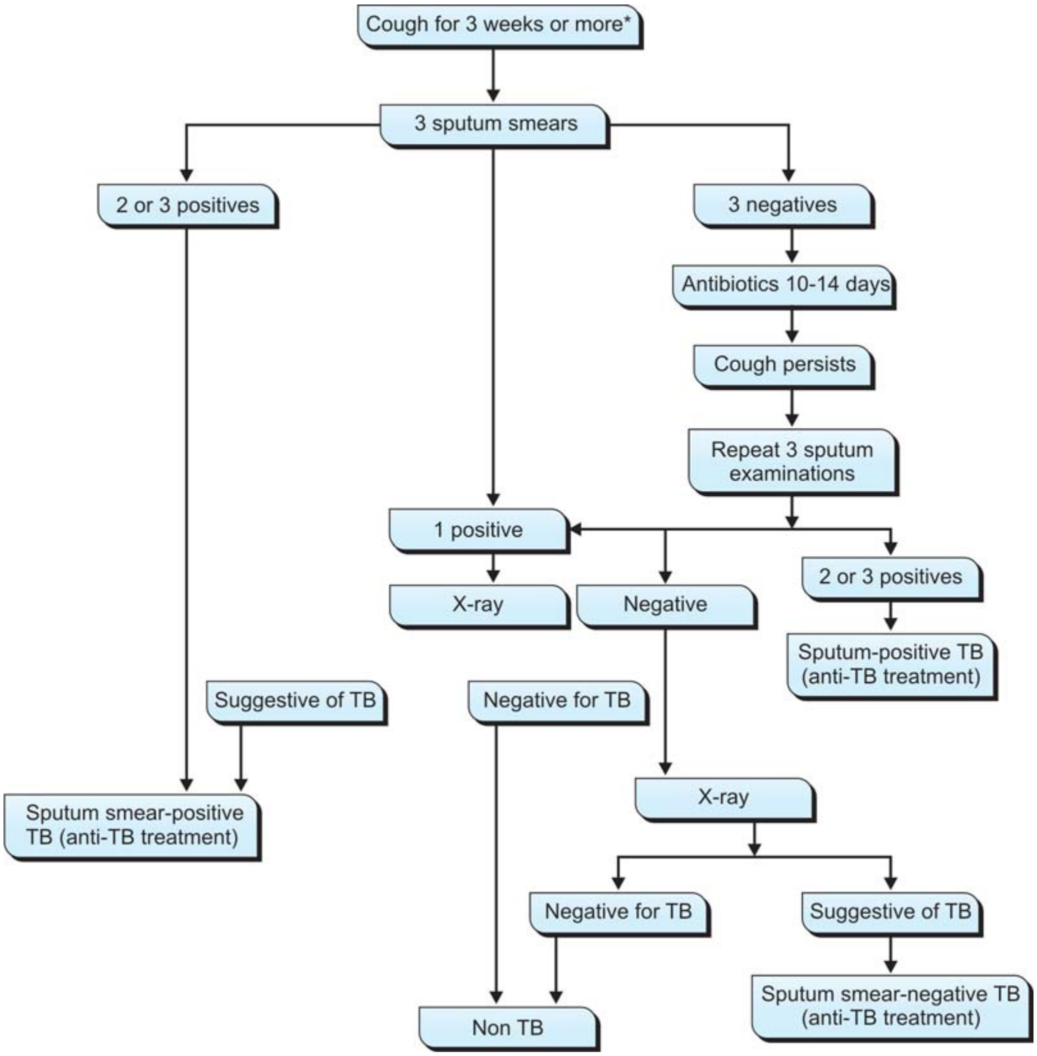
Diagnostic algorithm for pulmonary TB is shown in Flow chart 49.4.

Assurance

Effective Quality Assurance (QA) of the RNTCP sputum smear microscopy network is of crucial importance. QA is a total system consisting of internal Quality Control (QC), assessment of performance using External Quality Assessment (EQA) methods, and continuous Quality Improvement (QI) of laboratory services.

Quality Control (QC): Also called Internal Quality Assurance, includes all means by which the laboratory personnel performing TB smear microscopy, control the processes, including checking of instrument, new lots of staining solutions, smear preparation, grading, etc. It is a systematic internal monitoring of working practices, technical procedures, equipment, and materials, including quality of stains.

Flow chart 49.4: Diagnostic algorithm for pulmonary TB



Cough for 3 weeks or more*
3 sputum smears
2 or 3 positives
3 negatives
Antibiotics 10-14 days
Cough persists
Repeat 3 sputum examinations
1 positive
X-ray
Negative
2 or 3 positives
Sputum-positive TB (anti-TB treatment)
Suggestive of TB
Negative for TB
Sputum smear-positive TB (anti-TB treatment)
X-ray
Negative for TB
Suggestive of TB
Sputum smear-negative TB (anti-TB treatment)
Non TB

*Note: The duration is now 2 weeks wef 1st April 2009

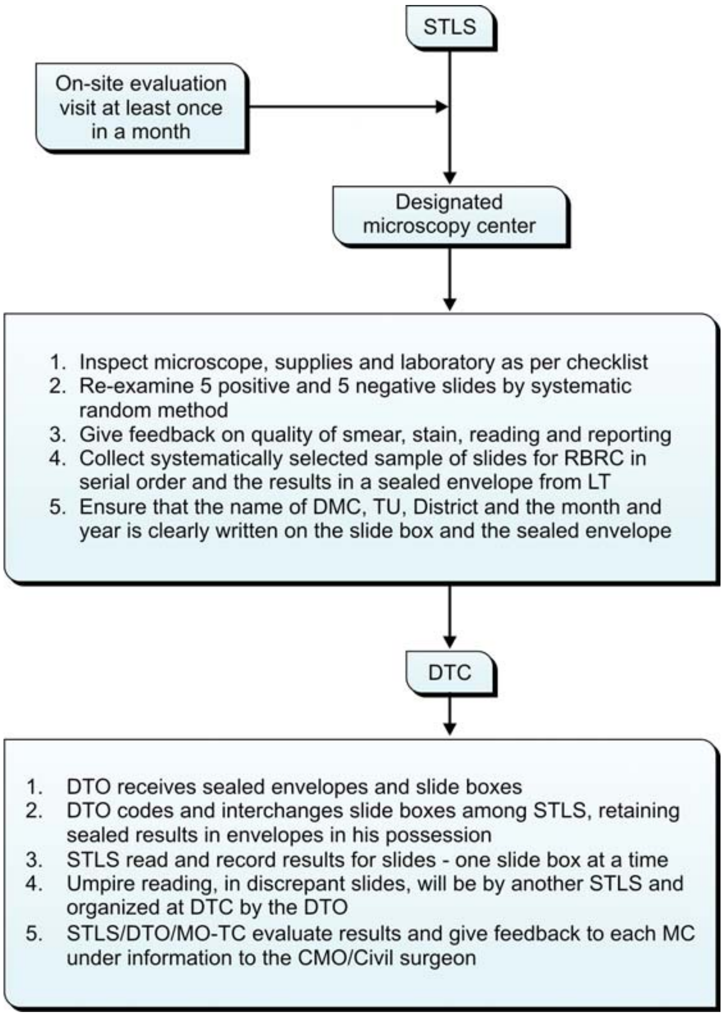
External quality assessment (EQA): A process to assess laboratory performance. EQA includes on-site evaluation of the laboratory to review QC and evaluation of entire process of smear microscopy, and random blinded rechecking of routine smears. EQA also allows participant laboratories to assess their capabilities by comparing their results with those obtained in other laboratories in the network through panel testing and rechecking of patient slides, using both unblinded and blinded procedures.

Quality improvement (QI): A process by which all components of smear microscopy diagnostic services are carefully analyzed with the aim of looking for ways to permanently remove obstacles to success. Appropriate data collection, data analysis, correct interpretation of the results and creative problem solving, are the key components of this process. It involves continued monitoring, identifying defects, followed by remedial action, including retraining when needed, to prevent recurrence of problems. QI mostly relies on effective on-site evaluation visits.

The network of DMCs is supported and supervised by regional/state laboratories (IRLs), and overseen by the NRLs.

Quality assurance network in sputum smear microscopy is shown in Flow chart 49.5.

Flow chart 49.5: Quality assurance network in sputum smear microscopy



STLS
On-site evaluation visit at least once in a month
Designated microscopy center
1. Inspect microscope, supplies and laboratory as per checklist
2. Re-examine 5 positive and 5 negative slides by systematic random method
3. Give feedback on quality of smear, stain, reading and reporting
4. Collect systematically selected sample of slides for RBRC in serial order and the results in a sealed envelope from LT
5. Ensure that the name of DMC, TU, District and the month and year is clearly written on the slide box and the sealed envelope
DTC
1. DTO receives sealed envelopes and slide boxes
2. DTO codes and interchanges slide boxes among STLS, retaining sealed results in envelopes in his possession
3. STLS read and record results for slides - one slide box at a time
4. Umpire reading, in discrepant slides, will be by another STLS and organized at DTC by the DTO
5. STLS/DTO/MO-TC evaluate results and give feedback to each MC under information to the CMO/Civil surgeon

External Quality Assessment

At the district level the activities of DTO, MO-TC and STLS for EQA of RNTCP laboratory network are:

- On-site evaluation of DMCs
- Blinded rechecking of DMC's slides at DTC, and
- Reporting the results of activities to LT and MO of the DMC and to STDC promptly.

The On-Site Evaluation (OSE) of DMC by the STLS includes a comprehensive assessment of laboratory safety, condition of the binocular microscope, adequacy of supplies, as well as the technical components of sputum smear microscopy, including preparation, staining and reading of smears. The frequency of on-site evaluation of any DMC is decided on the basis of its performance. On-site evaluation of every DMC is conducted at least once a month by the STLS of the respective TB Unit.

The DTO/MO-TC would also be supervising the DMC as per their tour program and hand over to MO of DMC the summary of observations and recommendations for corrective actions.

Random Blinded Rechecking (RBRC) at the district level involves the selection of a small sample of slides (sample size determined by the LQAS, i.e. lot quality assurance sampling methodology), which is representative of all slides of a DMC (both positive and negative). The original slide examination results by LTs are blinded and read by a STLS not belonging to the same TU to prevent bias.

The STDC/IRL conduct OSE, analyze district reports of RBRC during OSE and Panel testing of the districts.

Similarly NRL conduct OSE and Panel testing of the IRLs. (Details of QA activities of the NRL, IRL and district can be obtained from “Guidelines for Quality Assurance of smear microscopy for diagnosing tuberculosis”).

Checklists have been developed to assist supervisors during the field visit and to allow for the collection and analysis of standard data for subsequent remedial action.

TREATMENT

The objectives of tuberculosis treatment are:

- To decrease mortality and morbidity by ensuring cure, minimizing relapses and preventing the development of drug resistance
- To decrease infections and break the chain of transmission of infection
- To achieve the above whilst minimizing side effects due to drugs.

These objectives are achieved in RNTCP through intermittent (thrice weekly) treatment regimens given under direct observation for both pulmonary and extrapulmonary tuberculosis patients. Treatment regimens for tuberculosis have emerged as a result of controlled clinical trials in India and other parts of the world. It has been proven that thrice-a-week (intermittent) treatment is as effective as daily treatment and produces lesser side effects.

RNTCP provides standardized anti-TB treatment in three categories. Once the patient has been diagnosed as having TB, may be pulmonary or extrapulmonary, the MO is responsible for deciding the treatment regimen under one of the three categories depending on:

- Sputum smear results
- The history of previous anti-TB treatment
- Disease classification (pulmonary/extrapulmonary)
- Severity of illness.

Definition of Types of Cases

New

A TB patient who has never had treatment for tuberculosis or has taken antituberculosis drugs for less than one month.

Relapse

A TB patient who was declared cured or treatment completed by a physician, but who reports back to the health service and is now found to be sputum smear-positive.

Transferred in

A TB patient who has been received for treatment in a Tuberculosis Unit, after starting treatment in another unit where she has been registered.

Treatment after Default

A TB patient who received antituberculosis treatment for one month or more from any source and returns to treatment after having defaulted, i.e. not taken anti-TB drugs consecutively for two months or more, and is found to be sputum smear-positive.

Failure

Any TB patient who is smear-positive at five months or more after starting treatment. Failure also includes a patient who was treated with Category III regimen, but who becomes smear-positive during treatment.

Chronic

A TB patient who remains smear-positive after completing a retreatment regimen.

Others

TB patients who do not fit into the above mentioned types. Reasons for putting a patient in this type must be specified.

Seriousness of Illness

The severity of the illness depends on the bacillary load, the extent and the anatomical site of the disease. The involvement of an anatomical site helps in classifying if the disease is severe, depending on whether it is life-threatening or has high risk of developing subsequent severe handicap or both. The following forms of extrapulmonary TB and smear-negative pulmonary TB are classified as “seriously ill” (Table 49.2).

Treatment Regimens

Various categories of treatment regimens are shown in Table 49.3.

Drugs and their Dosage

The most important drugs used in the treatment of TB are isoniazid (H), rifampicin (R), pyrazinamide (Z), streptomycin (S) and ethambutol (E). The dosage strength is shown in Table 49.4.

TABLE 49.2: List of extrapulmonary and smear-negative pulmonary TBs that are classified as "seriously ill"

Extrapulmonary TB classified as 'seriously ill'	*Smear-negative pulmonary TB classified as 'seriously ill'*
• Meningitis	• Miliary TB
• Pericarditis	• Extensive parenchymal infiltration
• Peritonitis	• Coinfection with HIV
• Bilateral or extensive pleural effusion	• Cavitary disease
• Spinal TB with neurological involvement	• All forms of pediatric sputum smear-negative pulmonary TB except primary complex
• Intestinal	
• Genitourinary	
• Coinfection with HIV	
• All forms of pediatric extrapulmonary TB other than lymph node TB and unilateral pleural effusion are considered to be seriously ill	

TABLE 49.3: Various categories of treatment regimens[@]

Category of treatment	*Type of patient*	*Regimen**
Category I	New sputum smear-positive Seriously ill** new sputum smear-negative Seriously ill** new extrapulmonary	$2H_3R_3Z_3E_3$ + $4H_3R_3$
Category II	Sputum smear-positive relapse Sputum smear-positive failure Sputum smear-positive treatment after default Others***	$2H_3R_3Z_3E_3S_3$ + $1H_3R_3Z_3E_3$ + $5H_3R_3E_3$
Category III	New sputum smear-negative, not seriously ill	$2H_3R_3Z_3$ + $4H_3R_3$

**The number before the letters refers to the number of months of treatment. The subscript after the letters refers* to the number of doses per week. The dosage strengths are as follows: H: Isoniazid (600 mg); R: Rifampicin (450 mg); Z: Pyrazinamide (1500 mg); E: Ethambutol (1200 mg); S: Streptomycin (750 mg). Patients who weigh 60 kg or more receive additional rifampicin 150 mg. Patients who are more than 50 years old receive streptomycin 500 mg. Patients who weigh less than 30 kg, receive drugs as per body weight. Patients in Categories I and II who have a positive sputum smear at the end of the initial intensive phase receive an additional month of intensive phase treatment.

**Seriously ill also includes, any patient, pulmonary or extrapulmonary who is HIV positive and declares his serostatus to the categorizing/treating medical officer. For the purpose of categorization, HIV testing should not be done.

***In rare and exceptional cases, patients who are sputum smear-negative or who have extrapulmonary disease can have Relapse or Failure. This diagnosis in all such cases should always be made by an MO and should be supported by the culture or histological evidence of current, active TB. In these cases, the patient should be categorized as "Others" and given Category II treatment.

[@] As per Oct 2010 decision, the Cat III regimen has been deleted and merged with Cat I.

TABLE 49.4: The dosage strength of different drugs

Medication	*Dose (thrice a week)*	*Number of pills in Combipack*
Isoniazid	600 mg	2
Rifampicin	450 mg	1
Pyrazinamide	1500 mg	2
Ethambutol	1200 mg	2
Streptomycin	0.75 g	–

Drugs are supplied in Patient-Wise Boxes (PWB) containing the full course of treatment, and packaged in blister packs. The PWB have a color code indicating the category (Red for CAT I, Blue for CAT II and Green for CAT III). In each PWB, there are two pouches one for intensive phase (A) and one for continuation phase (B). For the intensive phase, each blister pack contains medicines for one dose. For the continuation phase, each blister pack contains one week's supply of medication. The drugs for extension of the intensive phase (prolongation pouches) are supplied separately.

For adults, drugs will be given in the recommended number of pills/capsules irrespective of body weight. However, for patients weighing more than 60 kilograms, an additional capsule of rifampicin 150 mg will be added to the treatment regimen. Patients who are more than 50 years old receive streptomycin 500 mg and patients who weigh less than 30 kg receive drugs as per body weight.

For children, the drugs will be given according to the body weight. Patient-wise boxes for children is being developed, however until these are available, the drugs are given to children as per body weight. The recommended dosages for children are given in section on Pediatric TB.

Regimen for Non-DOTS (ND) Treatment in RNTCP Areas

In RNTCP areas, all/most patients would be getting DOTS regimen. Unobserved rifampicin should not be given under any circumstance. However, RNTCP non-DOTS treatment (self-administered non-rifampicin containing regimen) may be needed in exceptionally few cases (e.g. adverse reaction to rifampicin and pyrazinamide). To facilitate registration of patients started on RNTCP Non-DOTS regimens, a tuberculosis treatment card should be filled. Up to a maximum of 5% of patients may get Non-DOTS treatment in an RNTCP area. Every effort should be made to minimize Non-DOTS, so that all patients are provided superior regimen under DOTS. The justification for initiating patient on non-DOTS treatment should be specified in the "Remarks" column of the treatment card and TB register. The prescribed Non-DOTS treatment regimen and dosages are presented below.

Non-DOTS Regimen 1 (ND1): 12-months conventional chemotherapy regimen, with streptomycin given in the first two months. This is given to patients who are: Cases of sputum smear-positive pulmonary TB and for seriously ill cases of smear-negative and extrapulmonary TB.

The treatment consists of 12-month conventional chemotherapy. The initial intensive phase lasts for two months and the continuation phase for 10 months. Isoniazid (300 mg) and ethambutol (800 mg) are self-administered by the patient daily for 12 months. Streptomycin 0.75 g per day (0.5 g for those over 50 years of age) is administered daily in the initial intensive phase for two months. Those who weigh less than 30 kg receive dosages calculated as per body weight.

Non-DOTS Regimen 2 (ND2): 12-month conventional chemotherapy regimen, without streptomycin for patients with smear-negative pulmonary TB who are not seriously ill; and for patients with extrapulmonary TB who are not seriously ill.

The treatment consists of 12-month conventional chemotherapy. Isoniazid (300 mg) and ethambutol (800 mg) are self-administered by the patient daily for 12 months.

Drug Administration

After the Medical Officer decides to treat the patient, the treatment card and patient identity card are prepared. The patient is put on treatment only after the verification of address by the Peripheral Health Worker (PHW) within a period of one week of diagnosis. The patient is also registered in the TB register during the supervisory visit of the STS within a period of one month from the start of treatment.

Prior to the starting of treatment, the MO of the Peripheral Health Institution (PHI) explains to the patient about the disease, dosage schedule, duration of treatment, the need for examination of contacts and frequency of follow-up sputum to monitor progress towards completion/cure. The MO also discusses with the patient to determine a DOT center, which is acceptable and easily accessible to the patient. Health education and motivation of the patient should be reinforced periodically during follow-up visits. The original treatment card is maintained at the PHI where the patient was started on treatment.

If the patient is to be treated by a DOT provider located outside the premises of PHI, a duplicate card will be prepared and given to the DOT provider to record all necessary information. The Medical Officer of the PHI will give the Patient-Wise Box (PWB) for the entire duration of treatment to the PHW. Issue of the PWB to the PHW will be duly recorded in the stock register maintained at the health facility. The PHW visits the house of the patient (definitely within a week) and has a detailed dialogue with the patient and other members of the family, emphasizing the treatment schedule, importance of regular uninterrupted drug intake, completion of the course of treatment, possible intolerance, etc. as well as the need for check-up of contacts. The treatment is initiated after this visit by PHW or community volunteer. For drug administration, a convenient location is decided mutually between the PHW and the patient.

Either of two cycles—Monday, Wednesday and Friday; or Tuesday, Thursday and Saturday—is fixed as days for drug administration. All doses in the intensive phase must be taken under observation of the DOT provider. The patient must be contacted within one day of missing a dose during the intensive phase. The dose missed on the specified day in the intensive phase can be administered on the following day. In the continuation phase, the first dose of the week should be taken under direct observation and the subsequent doses for the week are self-administered. On the next scheduled visit, the empty blister pack should be collected by the DOT provider before giving the next weekly dose. The patient must be contacted and retrieved for treatment within a week of missing a dose in continuation phase. All the empty blister packs (of IP and CP) should be retained in the PWB.

Treatment cards should be organized at DOT centers according to the day of scheduled observation and the phase of treatment (i.e. intensive phase and continuation phase). The cards should be organized in such a manner that the cards of patients who do not present for treatment will be apparent on the same day, and appropriate action for their retrieval can be taken.

As regards the administration of streptomycin injections at the peripheral level, the policy will be to entrust this responsibility to the Auxiliary Nurse Midwife (ANM) or equivalent at the subcenter level or to any registered medical practitioner who is acceptable and accessible to the patient. If the same is not possible, the patient has to come to the PHC/CHC or any other nearest health institution. The streptomycin injection should be given using disposable or sterilized syringes and needles.

The DOT provider records the drug administration, and refers the patient to the microscopy center for follow-up sputum examinations. He also enquires about any drug reaction and refers the patient to the MO if needed.

Side Effects

Serious side effects of anti-TB drugs are less with intermittent chemotherapy. Drugs should not be administered on empty stomach. DOT providers should identify common side-effects early and report to the medical officer.

Special Situations

Management of TB patients on DOT in special situations is described below.

Hospitalization

General policy of RNTCP is to treat patients on ambulatory basis. However, occasionally the general condition of the patient may be serious enough to require hospitalization. For example, in patients with pneumothorax or large accumulations of pleural fluid leads to breathlessness, massive hemoptysis, etc. These patients can be managed in general hospitals.

All indoor patients are to be treated with RNTCP regimens. The treatment is given using prolongation pouches, which will be supplied by DTO through the STS of the TU in which the indoor facility is situated. On discharge, patients may be given a maximum of three doses (one week drug supply) to cover the intervening period prior to their continuation of treatment at their respective DOT Center, which may/may not be in the same TU/district, hence ensuring no interruption in treatment. All indoor patients treated under RNTCP, should be registered under the local TU in which the indoor facility is located. If the patient resides outside the TU/district, on discharge she will be transferred out for continuing treatment.

Treatment of TB during Pregnancy and Postnatal Period

- Streptomycin should not be given; other drugs used in RNTCP are safe
- Breastfeeding should continue regardless of the mother's TB status
- Advise the mother to cover her mouth, if she is smear-positive, while breastfeeding the baby
- Chemoprophylaxis for the baby is recommended if mother is sputum smear-positive.

Treatment in Patients with Renal Failure

- Rifampicin, isoniazid and pyrazinamide can be safely given
- Streptomycin and ethambutol, if given, should be closely monitored with reduced dosage under the supervision of the treating physician.

Treatment in Women Taking Oral Contraceptive Pills

- Rifampicin decreases the efficiency of oral contraceptives; switch to another method of contraception.

Directly Observed Treatment (DOT)

Directly observed treatment is one of the key elements of the DOTS strategy. In DOT, an observer watches and supports the patient in taking their drugs. Direct observation ensures treatment for the entire course with the right drugs, in the right doses and at the right intervals.

DOT is necessary because at least one-third of patients on self-administered treatment fail to adhere to treatment and it is impossible to predict, which patients will take regular treatment.

The health worker or community volunteer who administers DOT is called the “DOT Provider”. DOT provider should be acceptable and accessible to the patient and is accountable to the health system. The “DOT center” is a place where DOT is given and is convenient to both patient and DOT provider. DOT can be provided by anyone other than the patient’s family members.

To ensure treatment success, patients must take all doses of treatment, in both intensive and continuation phases. During the intensive phase of treatment, each and every dose of medicine is to be taken under direct observation of the DOT provider.

After the patient takes the drugs under direct observation in the IP, the appropriate box in the treatment card is ticked (√) after the drugs are administered. If the patient misses a dose it is recorded “O” on the treatment card. If a patient does not take medication as scheduled in the IP, she should be traced and given the medication on the next day. The medication for the following day is then given as scheduled. If a patient misses any dose of medicine (does not come on two successive days in IP), these doses must be made up at the end of scheduled period and the duration of treatment will get prolonged.

During the continuation phase of treatment, all patients collect drugs from the DOT center (DOT provider) once a week on a designated day. One dose is administered under direct observation on the day of collection and the next two doses of the week are given to the patient for self-administration. An “X” is entered in the appropriate box to indicate the day the drugs were swallowed under direct observation. A line is drawn through the remaining days of the week (after the X) to indicate that the drugs for the remaining period of the week have been given (X......). The patients must present at the time of next week’s collection the empty strip/ blister pack of the drugs consumed. During the continuation phase, if the patient is late by a single day for drug collection, the dose may be given and other doses taken as scheduled. If the patient is late by two days or more days from the date on which he was scheduled to have the first directly observed dose of the weekly blister pack is given on the day he presents for collection the drug, the missed dose is marked as “O” on the treatment card. The drugs are given as when she returns for treatment and the missed doses must be made up at the end of scheduled period and the duration of treatment will get prolonged.

Patients who miss a dose must be contacted and put back on treatment through home visits. This should be done by the health staff or community health worker no later than the day after the patient was due to come for treatment in the intensive phase, and within a week of the missed dose in the continuation phase. It is important to take action immediately after knowing that the patient missed a dose. The reasons for the same interruption of treatment must be recorded in the treatment card.

Patient Flow for DOT

After receiving the sputum results, the MO of the Peripheral Health Institution (PHI) is responsible for the following measures:

- Establishing the diagnosis of tuberculosis
- Deciding the type of patient and category of treatment
- Explain to the patient about:
  The disease
  - The treatment (dosage schedule, duration, common side effects and methods to prevent them)
  - The need for examination of contacts (especially, if patient is smear-positive)
  - Frequency of monitoring of progress until cure
  - Importance of DOT
- Determines the DOT center and the DOT provider
- Initiates the tuberculosis treatment card (in duplicate when required) and the TB identity card
- Make the patient-wise box available at the DOT center along with the TB treatment card, TB identity card and sputum containers for morning samples of follow-up sputum examinations.

For the purpose of identifying a suitable DOT provider and an appropriate DOT center, a DOT directory should be maintained at PHI level. This directory should contain a locality-wise list of DOT centers/DOT providers in the area and should be updated regularly. The place identified for DOT (DOT Center) and name and designation of the DOT provider should be entered in treatment card in the space provided.

If the patient is to be given DOT by a PHW/ community DOT provider, the MO of the PHI where the patient is prescribed treatment, will send a duplicate copy of the treatment card along with the patients-wise box. The PHW visits the house of the patient as soon as possible (in no case later than one week) for confirmation of the address. This opportunity is used for a detailed dialogue with the patient and other members of the family, emphasizing on points similar to the ones mentioned above (for the MO-PHI) and screening of contacts. The initial home visit should be recorded in treatment card in the space provided. A convenient location for drug administration and a suitable DOT provider is decided mutually by the PHW and the patient.

The community DOT provider will be provided with the duplicate TB treatment card along with sputum containers (for morning samples of follow-up sputum examinations) and PWB. If untrained, on the spot training has to be done for the community DOT provider regarding directly observed treatment, adverse reactions, follow-up sputum examination and recording drug intake. The DOT provider should also be trained to give health education and motivation messages to the patient. The PHW is responsible for supervising and ensuring DOT and updating of the original card at the PHI on a fortnightly basis.

In case the patient misses any dose, PHW would have to take retrieval actions in case the community DOT provider fails to retrieve the patient. If the DOT provider is unsuccessful in retrieving such patients, it should be reported to the next level of supervisors (e.g. MPW, MO-PHI, STS, MO-TC, etc.). If the patient misses DOT on two occasions in the intensive phase, DOT provider should arrange a visit by the MO-PHI to the patient's home, so that the MO-PHI can review the reasons for the same, give intensive counseling to the patient and, if required, ensure that DOT is made more convenient for the patient.

The MO of the PHI (where treatment card was initiated) and the STS should also supervise DOT on a regular basis and support the PHW in patient retrieval. DTO and MO-TC should support them in their efforts through field-visits.

The DOT provider records the days the drugs are administered in the tuberculosis treatment card at the time of drug intake, and refer the patient to the DMC when follow-up sputum examinations are due. DOT provider also enquires about drug reactions and, if necessary, refers the patient to the MO.

Monitoring of Patients

Sputum smear microscopy is much more informative than radiology in monitoring the progress of chemotherapy. Hence, the patient should be referred for follow-up sputum examinations at the prescribed intervals. Other investigations like ESR, antibody detection, etc. are unreliable and have no role in diagnosing and/or evaluating the progress or results of treatment.

Follow-up Smear Examination

Follow-up of the patients is done as detailed below.

New smear-positive patients: Two smears are examined each time during follow-up. The first follow-up sputum examination is done at the end of two months of intensive phase. On the 22nd dose in intensive phase, the patient is given a sputum container and instructed to bring the early morning sample. The patient brings the sputum sample when he comes for the 23rd dose in the intensive phase when a spot sample is also collected. The results of both the smear examinations will be available at the next visit of the patient. If both smears are negative, the patient will be put on the continuation phase. If either of the smears is positive, the intensive phase will be extended by one more month, and sputum examination will be repeated at the end of the third month. Thereafter, the patient is put on the continuation phase regardless of his/her sputum status at the end of the extended intensive phase. Subsequent follow-up smear examinations are done after two months into continuation phase and if found positive the patient is declared as a treatment failure, re-registered and started on the retreatment regimen afresh. If the follow-up sputum is negative, the continuation phase is completed and smear examination repeated at the end of treatment. The sputum should generally be collected at the time of collection of the 16th blister so that the results are available at the time of supply of the last week's blister pack. Results of end of treatment sputum should be available not later than one week of completion of treatment.

Retreatment patients: The first sputum smear examination is done at three months after beginning of the intensive phase. On the 34th dose of the intensive phase the patient is given a sputum container and instructed to bring the early morning sample. The patient brings the sputum sample when he comes for 35th dose in the intensive phase when a spot sample is also collected. The results of both the smear examinations will be available at the next visit of the patient. If both smears are negative, the patient will be put on the continuation phase. If either of the samples is positive, the intensive phase of treatment will be extended by one more month, and another smear examination will be done at the end of the fourth month of treatment. Thereafter, the patient is put on the continuation phase regardless of his sputum status at the end of four months of the intensive phase. Subsequent follow-up sputum examinations are done after two months into continuation phase. Irrespective of the results of the follow-up smear examinations, the patient continues and completes the treatment when a final follow-up sputum smear is done. The sputum should generally be collected at the time of collection of the 20th blister so that the results are available at the time of supply of the last week's blister pack.

Smear-negative patients: Two smears are examined during the follow-up visit at the end of two months of the intensive phase and again at the end of treatment. If the patient becomes sputum smear-positive at the end of IP or at the end of treatment, his outcome is "failure" and is started on retreatment Cat II regimen after registration.

Treatment Outcome

The patient's treatment outcome is identified by reviewing her/his tuberculosis treatment card. The treatment outcome and the date the patient stopped treatment is written in the appropriate column in the tuberculosis treatment card. The date on which the patient stopped treatment is the date of the last dose of drugs taken.

The duplicate TB treatment card and the used/partially used PWB of the patient should be immediately returned by the PHW to the PHI. The MO of the PHI should record the treatment outcome in the treatment card and sign it. The treatment card of the patients whose outcome has been declared and partially used PWBs, if any, should be handed over to the STS during his routine monthly visits.

It is the responsibility of the STS to ensure that:

- The tuberculosis treatment cards reach the TB Unit from the treatment centers as soon as the treatment outcome is recorded and within a maximum of one month time.
- The treatment outcome is recorded in the TB Register within one month of the completion of the treatment in the case of cured and treatment completed cases. Similarly, the outcomes of patients declared defaulted or died should be recorded within one month of the event.
- Partially used PWBs, if any, is returned to the DTC for reconstitution.

Every patient started on treatment has to be given one and only one treatment outcome.

Patients whose outcome is identified as failure should be started on Cat II treatment afresh.

Determination of treatment outcomes are shown in Table 49.5.

MANAGEMENT OF PEDIATRIC TUBERCULOSIS UNDER RNTCP

Introduction

Childhood TB is a reflection of the prevalence of sputum smear-positive PTB and the extent of transmission of TB infection in the community. Children are likely to suffer from more serious forms of TB and are more likely to die if not treated properly. Reliable data on disease incidence and prevalence is, however, not available due to the difficulties in diagnosis of pediatric TB under field conditions.

TABLE 49.5: Determination of treatment outcomes

- If the patient Then the treatment outcome is identified as cured
- Was registered as pulmonary smear-positive, completed treatment and had negative smear cured results on two occasions, one of which is at end of treatment
- Was registered as pulmonary smear-positive, completed treatment with negative smears at the treatment completed end of the intensive phase but none at end of treatment
- Was registered as pulmonary smear-negative or extrapulmonary, and completed treatment
- Was known to have died from any cause whatsoever while on treatment died
- Was registered as pulmonary smear-positive CAT I, and was smear-positive at five months or later*
- Was registered as pulmonary smear-positive CAT II (retreatment), and was smear-positive at Failure five months or later of CAT II treatment
- Was registered as pulmonary smear-negative or extrapulmonary on CAT III, but was smear-positive any time during treatment*
- Has not taken drugs for more than two months consecutively any time after starting treatment Defaulted
- Was transferred to another TU/district and his/her treatment Transferred out outcome is not available

*Also, re-registered immediately as Category II and started on the retreatment regimen

Diagnosis

TB should be suspected among children presenting with fever and/or cough for more than three weeks, with or without weight loss or no weight gain; and history of contact with a suspected or diagnosed case of active TB disease within the last two years. Diagnosis should be based on a combination of clinical presentation, sputum examination wherever possible, Chest X-ray (PA view), Mantoux test (1 TU PPD RT23 with Tween 80, positive if in duration >10 mm after 48–72 hours) and history of contact. Diagnosis should be made by a medical officer and the existing RNTCP case definitions be used for all cases diagnosed. Purified protein derivative would be supplied by CTD to district headquarters.

Children showing neurological symptoms like irritability, refusal to feed, headache, vomiting or altered sensorium may be suspected to have TB meningitis.

Use of currently available scoring systems is not recommended for the diagnosis of TB among children. Where diagnostic difficulties are faced, the child should be referred to a pediatrician for further management.

Treatment of Pediatric TB

DOTS is the recommended strategy for treatment of TB and all pediatric TB patients should be registered under RNTCP. Intermittent short course chemotherapy given under direct observation should be used in children, as in adults.

RNTCP treatment categories and regimens for children are shown in Table 49.6.

In patients with TBM on Category I treatment, the four drugs used during the intensive phase should be HRZS (instead of HRZE) due to poor penetration of blood brain barrier by ethambutol. In TBM and spinal TB with neurological complications continuation phase of treatment should be given for six to seven months, thus extending the total duration of treatment to eight to nine months.

Steroids should be used initially in hospitalized cases of TBM and TB pericarditis and reduced gradually over six to eight weeks.

In all instances, before starting a child on Category II treatment, she should be examined by a Pediatrician or TB expert, wherever available.

As recommended by WHO, and in view of the growing evidence that the use of ethambutol in young children is safe, ethambutol is to be used as per RNTCP regimen for all age groups.

To assist in calculating required dosages and administration of anti-TB drugs for children, the medication would be made available in the form of patient-wise boxes, linked to weight bands. The recommended dosages for thrice weekly regimen in children are as follows: Isoniazid 10 to 15 mg/kg; Rifampicin 10 mg/kg; Pyrazinamide 30 to 35 mg/kg; Ethambutol 30 mg/kg and Streptomycin 15 mg/kg.

TABLE 49.6: RNTCP treatment categories and regimens for children

Treatment category	*Types of patients*	*Treatment regimen****	
		IP	*CP*
Category I	New sputum smear-positive PTB New sputum smear-negative PTB, seriously ill* New extra-PTB, seriously ill*	$2H_3R_3Z_3E_3$**	$4H_3R_3$
Category II	Sputum smear-positive relapse Sputum smear-positive treatment failure Sputum smear-positive treatment after default	$2H_3R_3Z_3E_3S_3$ $+ 1H_3R_3Z_3E_3$	$5H_3R_3E_3$
Category III	New sputum smear-negative, not seriously ill** New extra-PTB, not seriously ill**	$2H_3R_3Z_3$	$4H_3R_3$

*In children, seriously ill sputum smear-negative PTB includes all forms of sputum smear-negative PTB other than primary complex. Seriously ill EPTB includes TB Meningitis (TBM), disseminated TB, TB pericarditis, TB peritonitis and intestinal TB, bilateral extensive pleurisy, spinal TB with or without neurological complications, genitourinary TB, and bone and joint TB.

**Not seriously ill sputum smear-negative PTB includes primary complex. Not seriously ill EPTB includes lymph node TB and unilateral pleural effusion.

***Prefix indicates month and subscript indicates thrice weekly.

For monitoring treatment, follow-up sputum examinations are to be performed with the same frequency as in adults. Clinical or symptomatic improvement is to be assessed at the end of the intensive phase of treatment and at the end of treatment. Improvement should be judged by the absence of fever or cough, a decrease in the size of lymph node(s), weight gain, etc. Radiological improvement is to be assessed by chest X-ray examination in all smear-negative pulmonary TB cases at the end of treatment.

Chemoprophylaxis

Recent infection with tubercle bacilli is one of the risk factors for disease development. The younger the child, the higher is the risk of breakdown of infection into disease. Therefore, household contacts of smear-positive TB cases, especially those below 6 years of age, must be screened for the symptoms of tuberculosis. In the case of symptoms being present, the diagnostic algorithm for pediatric TB should be followed and the child should be given a full course of anti-TB treatment if s/he is diagnosed as a TB case. For asymptomatic children under 6 years, chemoprophylaxis with isoniazid (5 mg per kg body wt) should be administered daily for a period of six months. This is regardless of the BCG vaccination status.

Role of BCG Vaccination

Effective treatment of infectious patients under DOTS protects children against all forms of TB. The most effective way to prevent TB is to ensure that sputum smear-positive patients are cured. To protect contacts of smear-positive cases should be screened and managed as described above.

BCG vaccine is an attenuated strain of tubercle bacilli. After in depth reviews, it was concluded that though BCG may not protect against TB of lung, which occurs mostly in adults, it could provide substantial protection against the childhood forms of TB, such as tubercular meningitis, miliary TB. In India, it is recommended to give BCG vaccination to all children preferably at birth as part of National Immunization Schedule to give the benefit of protection against the childhood forms of TB (refer to National Immunization Schedule, Govt of India).

MANAGEMENT OF EXTRAPULMONARY TUBERCULOSIS

Extrapulmonary Tuberculosis (EPTB) comprises about 10 to 15% of all new TB cases in our country. Among them, 75% have lymph node or pleural TB.

A person with extrapulmonary TB may have symptoms related to the organs affected, such as swelling of lymph nodes, occasionally with discharge of pus, pain and swelling of the joints; headache, fever, stiffness of the neck and mental confusion when the brain or meninges are involved. In addition, the following general symptoms like weight loss, fever, particularly with the rise of temperature in the evening and night sweats may be present.

Patients with suspected EPTB should be referred to a competent medical practitioner for expert opinion. Diagnosis of such patients may be made by using appropriate diagnostic procedures [such as Fine Needle Aspiration Cytology (FNAC)/biopsy/culture from the site of disease) as well as clinical methods. Patients with EPTB who also have cough of any duration, should have three sputum samples examined. If the smear result is positive, the patient is classified as pulmonary TB.

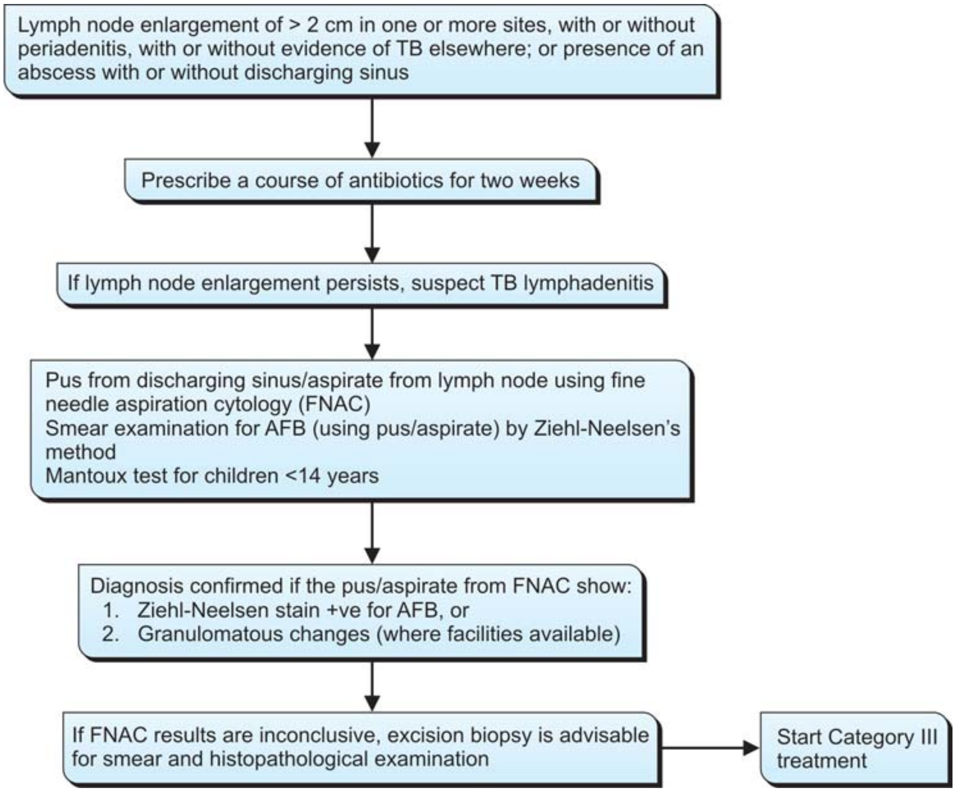
Intermittent short-course chemotherapy regimens of six to nine months are recommended internationally for all forms of extrapulmonary TB. In cases of TBM, initial hospitalization is recommended. In TBM, ethambutol should be replaced by streptomycin in the intensive phase and continuation phase of the treatment is for six to seven months. Adjunctive steroids may be useful in pericardial and meningeal TB.

Management of TB Lymphadenitis

Lymph node TB usually presents as slowly progressive, painless enlargement of the lymph nodes of neck, sometimes of axilla or groin. Cervical lymph node TB is the most common manifestation of extrapulmonary form of TB. Lymph node involvement of more than one group is common. Individual nodes are firm and discrete though matting of nodes may occur and may progress to abscess and sinus formation if left untreated. Tubercular abscess is also called “cold abscess” since inflammation is uncommon. In addition, constitutional symptoms like fever, malaise, weight loss, anorexia, etc. may be present, but not invariably. This form of TB is more common in children and adults who are less than 30 years of age.

Diagnosis based on clinical findings alone can lead to overdiagnosis in a high proportion of cases. Therefore, attempt should always be made to confirm diagnosis by undertaking FNAC. This procedure can be undertaken wherever facilities are available. Refer to the diagnostic algorithm on the next page for details. In addition, sometimes chest radiograph may reveal mediastinal widening suggestive of hilar adenitis.

Flow chart 49.6: Diagnostic algorithm for TB lymphadenitis



Lymph node enlargement of > 2 cm in one or more sites, with or without periadenitis, with or without evidence of TB elsewhere; or presence of an abscess with or without discharging sinus
Prescribe a course of antibiotics for two weeks
If lymph node enlargement persists, suspect TB lymphadenitis
Pus from discharging sinus/aspirate from lymph node using fine needle aspiration cytology (FNAC)
Smear examination for AFB (using pus/aspirate) by Ziehl-Neelsen's method
Mantoux test for children <14 years
Diagnosis confirmed if the pus/aspirate from FNAC show:
1. Ziehl-Neelsen stain +ve for AFB, or
2. Granulomatous changes (where facilities available)
If FNAC results are inconclusive, excision biopsy is advisable for smear and histopathological examination
Start Category III treatment

Intermittent six-month short-course chemotherapy regimen has been proven to be very effective in the treatment of superficial TB lymphadenitis.

Paradoxical reactions in the form of persistence or enlargement of existing nodes or appearance of new nodes may occur in about one-fourth of cases during treatment as well as after completing treatment, and sometimes even a few months later. These reactions do not indicate treatment failure and probably represent an immune response to the release of mycobacterial products caused by the rapid bactericidal activity of the drug regimens. Therefore, extension or modification of treatment is not warranted as they usually regress spontaneously. Residual lymphadenopathy, after treatment completion has also been reported in about one-third of patients. Studies have shown that retreatment is required only if residual lymph node biopsy is bacteriologically confirmed as positive by culture for *Mycobacterium tuberculosis*. As culture facilities are not available everywhere, FNAC may be resorted to. However, the granulomatous changes may persist for a long time even after adequate treatment. Hence, the decision to start retreatment cannot be based on histopathological proof alone. The relapse rates after SCC are reported to be quite low.

Diagnostic algorithm for TB lymphadenitis is shown in Flow chart 49.6.

Management of Pleural TB

Patients presenting with chest pain with or without difficulty in breathing for more than two weeks should be referred for chest radiograph. Constitutional symptoms like fever, anorexia, loss of appetite may be present, but not invariably. If chest X-ray is suggestive of pleural effusion, pleural aspiration should be performed for biochemical, cytological and smear examination by Ziehl-Neelsen stain for confirmation of diagnosis. Where available, pleural biopsy may be performed.

Patients with unilateral pleural effusion are treated with Category III regimen. Bilateral or extensive effusions are classified as seriously ill forms of extrapulmonary TB and treated with Category I regimen.

MANAGEMENT OF PATIENTS WITH HIV INFECTION AND TUBERCULOSIS

People coinfected with HIV and TB have a higher risk of developing TB disease. Irrespective of HIV status, RNTCP diagnostic algorithm should be followed for all TB suspects. Anti-TB treatment is the same for HIV-infected persons as it is for HIV- negative TB patients. Hence, they should be treated with RNTCP regimens. All new TB cases known to be HIV-positive are classified as seriously ill and treated with Category I regimen. The retreatment cases are to be treated with Category II regimen.

It is important to maintain confidentiality regarding HIV status of individuals, including TB suspects and patients, in order to prevent stigmatization and discrimination. TB patients should be encouraged to voluntarily share their HIV status with the treating physician for the purpose of taking clinical decisions like categorization for the treatment of TB, treatment of other opportunistic infections and provision of ART. The HIV-positive status should not be disclosed by the treating physician to any other staff involved in RNTCP. In addition, the HIV-positive status should not be mentioned in any RNTCP records.

TB patients who have other HIV-associated opportunistic infections, or report risk behavior for HIV, should be offered referral to the nearest Voluntary Counseling and Testing Center (VCTC) for voluntary counseling and HIV testing. Routine HIV testing of all TB suspects/patients is not the national policy.

DOTS in TB-HIV

Directly observed treatment with effective short-course treatment regimen is even more important for HIV-positive TB patients. Self-administration of treatment is associated with higher case fatality rates. Hence, a DOT strategy that ensures adherence to therapy should be used for all HIV-positive TB patients.

The relapse rate of TB in HIV-positive TB patients who complete directly observed treatment with short-course regimen is low, although slightly higher than in HIV-negative TB patients. However, this increase is more likely to be due to reinfections rather than true relapse of disease. Treatment interruptions, due to higher occurrence of adverse drug reactions or intercurrent opportunistic infections, could also lead to an increased risk of relapse of TB.

Antituberculosis Therapy and Antiretroviral Therapy (ART)

The antiretroviral drugs, which are used in HIV-positive patients, are effective in slowing down the progress of HIV disease and prolonging life. These drugs are grouped as Nucleoside Reverse Transcriptase Inhibitors (NRTIs), Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs), nucleotide reverse transcriptase inhibitors, Protease Inhibitors (PIs) and fusion inhibitors. The current recommendations on ART are to use a triple drug combination. A combination of, Stavudine/Zidovudine plus lamivudine plus Efavirenz/Nevirapine is usually used. (For details refer to National AIDS Control Organization guidelines).

Protease inhibitors and nonnucleoside reverse transcriptase inhibitors may inhibit or induce cytochrome P450 isoenzymes and thus alter the serum concentration of rifamycins. Rifamycins induce cytochrome P450 and substantially decrease blood levels of these antiretroviral drugs. Dose adjustments for nevirapine coadministered with rifampicin has not been established. Hence, coadministration of Rifampicin with any of the protease inhibitors (ritonavir, indinavir, nelfinavir) or nonnucleoside reverse transcriptase inhibitors (nevirapine) should be avoided.

All TB patients coinfected with HIV should be treated with a rifampicin containing treatment regimen under DOTS. In TB patients coinfected with HIV, TB treatment should be completed prior to starting ART, unless there is a high risk of HIV disease progression and death during the period of TB treatment (i.e. a CD4 count < 200/mm^3 or the presence of disseminated TB). In a patient who has been on treatment with rifampicin, at least two weeks should have lapsed after the last dose of rifampicin before starting protease inhibitor or nonnucleoside reverse transcriptase inhibitors. This time gap is necessary for reduction of the enzyme-inducing activity of rifampicin prior to the commencement of anti-retroviral drugs.

In patients with very low CD4 counts requiring concomitant administration of ART and anti-TB treatment, the ARV regimen should be modified by replacing nevirapine with efavirenz. On the completion of TB treatment, such patients can be switched back to nevirapine.

Operationalization of VCTC-RNTCP Cross-Referral Linkages (VCTC now called ICTC)

Service linkages between VCTC and RNTCP diagnostic and treatment centers are the most important area of coordination between the HIV/Acquired Immuno-deficiency Syndrome (AIDS) and TB Control program. RNTCP visualizes VCTC as a PHI referring TB suspects irrespective of their serostatus. VCTC's will identify and refer suspected TB cases to the RNTCP Designated Microscopy Centers. Tuberculosis patients who have other HIV-associated opportunistic infections or report risk behavior for HIV, would be offered referral to VCTC for counseling and diagnosis of HIV infection.

Steps for Operationalization

- Ensure that the VCTC, DMC and DOT center are in the same campus so that referral linkages are easily established. In case they are not in the same campus, efforts should be made to establish effective referral linkages between them.
- Ensure that all the VCTC and RNTCP staff members are trained in TB/HIV.
- Provide VCTC with RNTCP laboratory forms for sputum examination to refer patients to DMCs.
- Provide VCTC with a list of DMCs and DOT centers in the district/state.
- Ensure IEC materials on TB are displayed and available at the VCTCs. IEC material on HIV provided by State AIDS Control Society (SACS) would be displayed at all RNTCP sites.
- Confidentiality of HIV status must be ensured at all levels by all staff. Remember that the HIV status of a patient should not be mentioned in the treatment card, TB Laboratory Register or any other document. Do not use any symbols/codes for the identification of HIV-positive persons.
- The VCTC counselors are to visit the DMCs, and the STSs are to visit the VCTCs to follow-up on referred cases.
- Monthly RNTCP Review meetings are to be attended by the VCTC staff. During this meeting information on cross referral and feedback on the utilization of the services, would be shared.
- State TB Officer, State VCTC Programme Officer, District TB Officer and District Nodal Officers (HIV/AIDS) to review TB/HIV coordination activities during their periodic field visits.

  For details, refer to guidelines on HIV/TB coordination.

Referral of Persons from VCTC to RNTCP

At VCTC

VCTC Counselors will identify persons with symptoms suggestive of TB disease amongst the clients. The counselor will ask each and every client for the history of cough for more than three weeks and other associated symptoms of TB. Patients, irrespective of their serostatus, having cough will be referred to a DMC for sputum examinations and in case of symptoms of extrapulmonary TB, the patient should be referred to a competent medical practitioner for expert opinion. The RNTCP sputum examination form will be filled in by the counselor. On the sputum examination form, the counselor should fill in all the required details including the name of VCTC, and take special care in obtaining and recording correct residential address of the patient. The counselor will not mention the HIV status of patient on the form or elsewhere, but shall encourage the patient to disclose his HIV status (if known) to the treating physician, in the interest of better case management. The sputum examination form is given to the patient with specific instructions on the location and timings of the DMC. The counselor should make a detailed note of the referral in the counseling register.

The counselor should impart information/counseling on TB to all VCTC clients and should document the same in the counseling register, irrespective of whether they have signs or symptoms of TB or not.

At Designated Microscopy Center (DMC)

Once the patient reaches the DMC, the same process would be followed as for any other TB suspect, i.e. the diagnostic algorithm of RNTCP would be followed. The laboratory technician would enter the details of the patient, including correct residential address and clearly mention the name of VCTC as the referring unit in TB laboratory register. After all the three sputum examinations are done, the results of the test are given to the patient. Patient would then go to the medical officer for further management.

In case of extrapulmonary TB, the VCTC would refer the patient to the medical officer for necessary investigations. After obtaining the test results, the medical officer would decide the further course of management.

If the patient has TB (pulmonary or extrapulmonary), treatment categorization is done as per the RNTCP treatment algorithm. Voluntary disclosure of the HIV status by the client should be encouraged. All new TB cases with known HIV-positive status, would receive RNTCP Category I regimen and retreatment TB cases will receive Category II regimen. Based on patient’s area of residence, these patients are referred for treatment to the nearest DOT center.

Referral of TB Patients to VCTC for HIV-Testing

TB patients who have signs/symptoms of other HIV-associated opportunistic infections, or report risk behavior for HIV would be offered referral by the medical officer to the VCTC. Thus, these diagnosed TB patients may be referred from DMC, DOT center, outpatient clinic, TB ward, TB clinic, etc. Sometimes the patient may simultaneously be investigated for TB and HIV. The doctor should first complete the investigations for TB and then refer for HIV investigations. While referring to the VCTC, the doctor should write a referral note to VCTC in which the TB status of the person is mentioned. The referral of the TB patients to the VCTC for eliciting the HIV status for the sake of categorization should never be done.

Once the referred TB patient reaches VCTC, the same procedure will be followed as that for any other client attending VCTC. At the VCTC, the patient/client will undergo pretest counseling. HIV testing is done after obtaining informed consent. The details of the patient/client will be entered into the PID register and counseling register. HIV testing is done and the test results are handed over by the laboratory technician to the counselor. The counselor reveals the HIV test result to the patient/client with post-test counseling. The HIV test results are not revealed to any other person other than the individual.

For details of operationalization of VCTC-RNTCP cross-referrals linkages separate modules for TB/HIV compiled by the Central TB Division may be referred.

RECORDING AND REPORTING

Maintenance of accurate records and registers of patients and program activities; and reporting data to the state/central unit every quarter, is essential for the proper monitoring and management of RNTCP. RNTCP records and reports are standardized and provide the required information for managing the program effectively.

The following standardized records and reports are used in the RNTCP:

Forms

- *Laboratory form for sputum examination:* Kept at all the PHIs. It is filled generally by the MO of the referring health facility. Only one form is filled for each patient. Patient will report to the DMC along with the laboratory form. In case PHI is a sputum collection center, sputum samples are sent to the DMC along with the laboratory form. It is essential to indicate in the laboratory form whether the sputum has been sent for diagnosis or follow-up. In the former case, the patient's detailed address should be given so that if the patient does not return to the health institution and the sputum is found to be smear-positive, the patient can be traced. The Tuberculosis No. of all patients whose sputum is being examined for follow-up must be written in the space provided.
- *Tuberculosis treatment card:* The card is filled at the PHI when patient is initiated on treatment. This card contains important information about a patient. It features name, age, sex and address of the patient; type of disease; history of past anti-TB treatment; regimen prescribed; duration of treatment; amount of drugs to be given; results of sputum smear examinations before and during treatment; drugs administered during the intensive and continuation phases of treatment; treatment outcome of the patient; retrieval actions for missing doses; preventive treatment for children; details of X-ray or other tests for diagnosis of EP TB; and remarks. It also has information on the DOT provider, person conducting the initial home visit and the signature of the MO.
  It is kept at the peripheral health institution where the patient receives treatment (either at the district hospital, CHC, PHC, health post, etc.). For the patients who do not come to these health institutions and have to be given treatment at the subcenter or village level by the multipurpose worker/anganwadi worker/ASHA/community DOT provider, a duplicate card is made and given to the above health functionary who is directly supervising drug administration of the patient. Information regarding administration of drugs during the treatment will be entered on this card and in case a duplicate is used for this purpose, the information is transferred onto the main card kept at the health institution by the most peripheral health functionary/community volunteer, on a fortnightly basis. The STS transfers the relevant data, particularly the results of bacteriological examinations, from the treatment card to the tuberculosis register kept at the Subdistrict (TU) level. Once the patient completes treatment or if s/he dies, defaults or is transferred, it should be ensured that all the information has been entered in the original card, which is retained at the Peripheral Health Institution.
- *Patient's TB identity card:* It is completed for each patient who has a tuberculosis treatment card. It is kept with the patient. Information from the tuberculosis treatment card is used to complete the identity card. The front part of the ID card has patient information, name and address of the TU/district and patient's treatment details, including disease classification, type of patient, sputum results, category and information on the date of starting treatment. The back portion of the ID card has the results of follow-up sputum examination, appoint-

ment dates for visits for drug administration and treatment outcome. This information will help to continue treatment, in case the patient is transferred or admitted to any other health facility anytime during the treatment period.

- *Referral form for treatment:* This form is available at all DMCs. Medical officer of the Designated Microscopy Centers, which refer patients for treatment to other peripheral health institutions needs to fills in the top half of the form that includes the patient characteristics. Once the patient arrives, the receiving unit fills in the bottom half of the form, and sends it back to the referring unit. Information regarding the referral of patient should also be noted in the referral for treatment register or in the remarks column of the TB laboratory register.
- *Transfer form:* It is kept at all the PHIs administering treatment for TB. This form is to be used when transferring registered patients on treatment from one reporting unit to another. If a patient is being “transferred out”, a tuberculosis transfer form and a copy of the tuberculosis treatment card will be sent from the “transferring unit”, i.e. referring health facility/TU to the “receiving unit”, i.e. health facility/ TU where the patient will receive further treatment. This form has four parts and should be filled up in triplicate. The first part of the form contains information about the patient, her/his disease, treatment details and address of the transferring unit. This information should be used to complete a new tuberculosis treatment card for the patient, who would be reregistered as a “transfer in” case in the receiving unit. When the patient has reported to the receiving unit, the bottom (fourth) part of the form is completed by the receiving unit and returned to the transferring unit. The third and second parts are to communicate patients’ sputum results at the end of intensive phase and treatment outcome respectively to the transferring unit.
- *Mycobacteriology culture/sensitivity test form:* Request for culture/sensitivity tests would be sent to the reference laboratory by the DTO along with the patient or patient’s sputum samples in case of failure to respond to directly observed Category II treatment regimen.

Registers

- *Tuberculosis laboratory register:* It is kept at all designated TB microscopy centers. The tuberculosis laboratory register is used to record the results of sputum smear examinations. The LT assigns a laboratory serial number for each patient who has been referred to the laboratory for sputum microscopy. The following information about the patient is recorded: Date of sputum smear examination; full name; sex, age, name of the health facility that requested the examination (e.g. primary health center, medical college, private practitioner, NGO, etc.); complete address; reason for examination (diagnosis and follow-up); and the results of sputum smear examinations. The last two columns of the register are for the LTs signature and any remarks the LT or supervisor wishes to make. The remarks column is also used by the STS, enters tuberculosis number (TB No.) and category of treatment from the TB register. The remarks column can also mention in brief the action taken for patients belonging to other TU/ districts, e.g. “Referred for treatment to…” The laboratory technician should summarize the information on sputum smear examinations done during that month. This information should be summarized in the format at the end of each month, printed in the laboratory register itself. The STLS should write their monthly supervisory abstract after the last entry of the month. Patients from the following month should be started from the next new page.
- *Tuberculosis register:* It is kept at the tuberculosis unit, which is at subdistrict level and contains information on all TB patients registered in the area. The tuberculosis register is used to record the following information about the patient: TB No.; Date of registration; name (in full), address, age/sex; name of PHI; date of starting treatment; regimen/category; disease classification; type of patient; details of sputum examinations; treatment outcome with date; remarks; and summary at the bottom of the page. The tuberculosis register is maintained by the STS at the TU level. All TB patients, who are put on DOTS and non-DOTS, must be registered in the tuberculosis register so that all the patients in the unit are monitored. The STS should register the patients as early as possible, and in no case more than a month after starting treatment. The TB register should be updated by the STS during the supervisory visits to the PHI. The initial and subsequent information required for registration and updating of the tuberculosis register is obtained from the tuberculosis treatment card. Information from the TB register is used to compile the quarterly reports.
- *PHI-level supervisory register:* This is maintained at each PHI. All supervisors (STO, CDHO, DTO, MO-

TC, STS, STLS, etc.) should summarize their observations in the supervision register. The "summary of observations and recommendations of visit" is filled in triplicate. A copy of the summary is detached for future record of the supervisor, a copy is sent to the next higher level officer, and the third copy is left in the register, which should be reviewed during all subsequent supervisory visits to ascertain whether corrective actions were taken by the concerned MO-PHI.

- *Referral for treatment register:* It should be maintained in all big hospitals and medical colleges where large numbers of cases are expected to be diagnosed and referred for treatment to other reporting unit. The referring unit should receive feedbacks on patients referred to other TUs in the same district within 14 days and for patients referred outside the district/state within one month.
- *Stock register:* It is maintained at state/district/TU drug store. It is used for recording the information on the stock of drugs and consumables received and issued by the health unit. The register also mentions the batch numbers and date of expiry of drugs and consumables. The reconstituted PWBs should be recorded in the DTC stock register as receipts. The format of the register can be referred to in the "Standard Operating Procedures Manual for State Drug Stores."
- *Reconstitution register:* It is maintained at all the DTCs for recording the receipt of drugs of patients who have defaulted, died, failed treatment or transferred out. Such drug boxes are reconstituted and the details thereof are also recorded in the register. The format of the register can be referred to in the "Standard Operating Procedures Manual for State Drug Stores".

Reports

The quarterly reporting system used in RNTCP enables analysis of cohorts of patients. A cohort in this context is a group of patients who were registered for treatment in a specified area over a specified period of time. Under RNTCP, specified areas are TB unit, district, state and country. The specified periods of time are four quarters of a year and one calendar year itself. A quarter is a three month period with the first quarter starting on 1st January of the year and one year is divided into four quarters (1st, 2nd, 3rd and 4th). This information helps national, state and district levels to assess the performance and monitor the implementation of the program. Every patient initiated on RNTCP treatment is registered in the TB register. The cohort-based quarterly reports are initiated from the TU level. Using the information in the tuberculosis register, the senior tuberculosis supervisor, under the supervision of the medical officer-tuberculosis control, prepares quarterly TU-level reports. The MO-TC submits the report to the district tuberculosis officer, who, in turn, compiles the reports received from all tuberculosis units in the district and sends the district-level reports to the state tuberculosis officer and the Central TB Division electronically. Computers with the Internet facilities have been provided at all District TB Centers in the country for electronic transmission of reports.

At the state, district and TU-levels, following reports are used:

Quarterly report on new and retreatment case of tuberculosis: It includes the number of tuberculosis cases diagnosed and registered under DOTS regimens CAT I, II and III during a quarter. Every patient started on treatment and registered (except those typed as "transfer in") must be included. The case-finding data provides details of the new sputum-positive (age and sex distribution), new sputum-negative, extrapulmonary and retreatment cases registered during the quarter. It also includes information on patients belonging to the pediatric age group.

Quarterly report on sputum conversion of new and retreatment cases registered four to six months earlier: This report gives the proportion of smear-positive cases of the cohort registered in the previous quarter who became smear-negative or are still positive at two and three months of treatment. Although sputum conversion rates are determined for all different types of smear-positive patients (new smear-positive, relapse, failure and treatment after default), the most important evaluation is that of new sputum smear-positive patients. The sputum conversion rate is not only an indicator of the efficacy of the treatment regimen, but also of the effectiveness of program implementation.

Quarterly report on results of treatment of tuberculosis cases registered 13 to 15 months earlier: This report shows the various treatment outcomes (cured, treatment completed, died, failure, defaulted and transferred out) of all cases registered during the corresponding quarter.

Quarterly report on program management and logistics (TU/District/State): It indicates the status of involvement of PHIs, staff position and training, supervisory activities, referral activities, microscopy, treatment initiation, quality of DOTS implementation, Laboratory Quality Control Network (EQA), TB-HIV cross-referrals, medications, consumables and equipment in place. The district level report has additional information on the involvement of medical colleges and other sectors, IEC and financial management in the district. In addition to the information stated above the state level report also collects information on district internal evaluations performed during the quarter, details of training held at STDC/state level; state level drug stock and the availability of drug susceptibility testing facility in the state.

At the PHI-level, the following report is generated:

Monthly PHI report on program management, logistics and microscopy filled at all PHIs by the MO on the last working day of the month and sent to the CMO/CDHO with a copy to the concerned TU, on or before fifth of the next month. This report contains information on drugs and consumables, staff position, referral activities, microscopy activities, treatment initiation and status of microscope. This report is to be complied after physical verification of the stock. It is the responsibility of the MO-TC and STS to ensure that all PHIs submit their monthly reports on time. The DTO should collect copies of this report from the office of CMO/CDHO for the close monitoring of microscopy activities and logistics in the district on a monthly basis. The copies at the TU level shall be used for monitoring as well as preparation of quarterly reports.

SUPERVISION, MONITORING AND EVALUATION

A “Supervision and Monitoring Strategy” with specific indicators to monitor and evaluate the program at different levels with the objective to further improve the performance of RNTCP, is in place. The detailed strategy can be referred to in the “Strategy Document on Supervision and Monitoring.”

Effective supervision at all levels (central, state, district, sub-district, designated microscopy and DOT centers) is crucial to the successful implementation of the program. RNTCP lays out clear responsibilities to the respective staff at each level in relation to supervisory activities.

Role of Central TB Division

- The role of the Central TB Division includes supervision of the state level implementation and of the State TB Training and Demonstration Centre (STDC), monitoring and evaluation of overall performance of RNTCP throughout the country and regular reporting on RNTCP performance. Regular supervisory visits are also made to the states implementing RNTCP and to districts of “concern”. The CTD provides overall oversight of RNTCP and its activities, and provides technical and policy guidance to the program.
- At the State level, the STO, with the support of the Deputy STO and MO of State TB Cell (STC), is responsible for the planning, supervision, monitoring and evaluation of all TB control activities in the respective state. The STC/STDC staff together is expected to make supervisory visits to all the implementing districts every quarter.
  The state level program review meetings should be held quarterly and chaired by the Secretary Health. The major points that require attention at the review meeting should be prepared by the STO prior to the meeting and provided to the secretary in advance of the review meeting. STO is responsible for the submission of the consolidated state level RNTCP quarterly reports, which are sent to the CTD as per program guidelines. The STO is also responsible for sending feedback to all districts on their quarterly reports within 30 days of the end of the quarter.
- At the district level, the DTO, with the support of Medical Officer (MO) of the District TB Centre (DTC), is responsible for ensuring the quality of diagnosis, treatment, logistics and reporting in their respective district. DTOs should be full time for RNTCP activities. The DTO, along with the MO, are expected to undertake supervisory visits (three to five days in a week, i.e. 20 days in a month) to all the tuberculosis units and any medical colleges in the district every month, and all the Designated Microscopy Centres, Community Health Centres (CHCs), Primary Health Centres (PHCs) and other hospitals in the district every quarter. One subcenter from each PHC, and a proportion of the tribal subcenters, and participating NGOs and private practitioners should also be visited every quarter. They should also visit at least three randomly selected NSP cases and their DOT providers on every field visit day.
- The DTO will complete a tour diary containing all relevant findings of his/her supervisory visits. The DTO, and DTC MO if in place, will also write all relevant findings in the “Summary of observations” sheet in the RNTCP supervisory register held at the relevant PHI/DMC. One copy of the summary of observations will be held by the DTO for his/her record and the second copy will be sent to the respective CMO.
- The DTOs will also review the monthly activity reports of all MO-TCs, STLSs and STSs within the respective district during the monthly district level meeting of said staff. The monthly PHI reports should be available at these meetings.

Representatives of the other health institutions should also be called for this review. The date of the review should be fixed in advance. Minutes of these meetings should be kept by the DTO.

- The DTO is responsible for the consolidated district level RNTCP quarterly reports, which are sent to the State TB Cell (STC) and the Central TB Division (CTD) as per the program guidelines.
- The Chief Medical Officer (CMO) is also expected to review the program on a regular basis. Guidance on program review will be provided to the CMOs, and also to district collectors.
- At the TU level, the MO-TC, STS and STLS, are responsible for undertaking supervisory visits to all the peripheral health facilities, NGOs and PPs. The MO-TC is responsible for supervising the work of TU and of the STS and STLS, in addition to his/her other responsibilities. The MO-TC should reserve seven days in a month for field visits and visit all DMCs every month, and visit most of the participating private as well as public PHIs every quarter.
- The STS is responsible for the quality of case detection and treatment activities being provided by all the health facilities, both in the public and private sector, NGOs, including PPs, medical colleges and community volunteers under the respective TU. He/she is expected to visit all CHCs and PHCs every month and subcenters, NGOs/PPs and community workers every quarter.
- The STLS is responsible for the quality of sputum smear microscopy services provided by the DMCs under the respective TU. She is expected to visit all the DMCs under the respective TU at least once a month. The STLS is also expected to do blinded rechecking of slides at the DTC as per the roster put up by the DTO.
- The supervisory team at the TU (MO-TC, STS and STLS) are primarily responsible for the supervisory activities in their area of coverage. Though they may go individually for supervisory activity, some visits should be made as a team for better coordination. The DTO will also supervise the field units as per program guidelines. During supervisory visits, one observes and reinforces stipulated practices in the various components of the RNTCP as well as identifies and corrects inadequate performance and recording discrepancies, if any, before these become a major problem. The focus of supervisory visits is on education, coordination, motivation, facilitation and guidance with the overall objective of implementing corrective action.
- A supervisory checklist and list of key indicators (refer “Strategy document on supervision and monitoring”) are to be used to identify the administrative and technical problems systematically. The indicators relevant to different levels of program management are grouped to indicate.
  - Political and administrative commitment
  - Human resource
  - Diagnostic practices
  - Drugs
  - DOT and follow-up services
  - Recording and reporting
  - TB/HIV coordination
  - Supervision
  - IEC, and
  - Financial management.

Prioritization of Health Units to be Supervised

The important guiding criteria for prioritizing health units, which are to be supervised are:

- Low proportion of patients receiving directly observed treatment as per guidelines
- High proportion of patients who were wrongly categorized
- Sputum conversion rate for new sputum smear-positive patients at three months is less than 85%
- Cure rate for new sputum smear-positive patients is less than 80%
- High proportion of sputum-negative and extrapulmonary cases
- Low case detection of new sputum smear-positive cases
- High default, death or failure rate.

By and large, the health units should be sent prior information of the supervisory visit. However, some surprise visits to the health units should also be undertaken.

Monitoring

The program is monitored on a quarterly basis from reports, which include the report on case finding, sputum conversion, treatment outcomes and program management. The program has also evolved an in-built monitoring system.

The quarterly reports are analyzed using the list of indicators at all levels, from the PHI, TU level, district, state to the center. Detailed feedback on the performance of the districts is sent to the districts by the state at the end of every quarter in order to support the districts to improve performance. CTD gives additional feedback and helps in building the capacity of the state to monitor and evaluate the program in their respective states.

Besides the routine monitoring of the quarterly performance reports, the program undertakes specific measures to monitor the program implementation in the districts. These initiatives include:

"Internal Evaluation" of the Programme

Intensive supervision and monitoring at all levels is critical to the success of RNTCP. The state level "Internal Evaluation" is a tool for comprehensive review of the district program, with the purpose of giving specific recommendations to improve the program performance. "Internal Evaluations" of two districts per state per quarter are expected to be carried out in large states. During "Internal Evaluation" there is an objective assessment of program services and activities. The objectives are:

- To validate the cure rates of the district for the last reported quarter
- To assess the program performance as well as financial as well as logistics management
- To give recommendations for improving the quality of recording and reporting
- To give recommendations for improving the performance (with a timeframe).

"Central Level Evaluation" of the Districts

In addition to the state level driven internal evaluations, a centrally driven evaluation with the active participation of the respective states to carefully review the systems and program implementation of poorly performing districts is undertaken. The purpose of the enhanced monitoring process is not only to improve the performances of the districts in question, but also to identify generic problems and find solutions, which might be equally relevant to or applicable in other districts as well. This evaluation will also cover districts where excellent performance is being reported. This is in part to check the validity and correctness of the data and reporting, but also to find out best practices, which could then also be implemented in other districts. These evaluations are not meant to be an exercise in criticism or praise, but as a strategic tool leading to the systematic and systemic improvement in the implementation and performance of RNTCP.

National Review of the Programme

Apart from the routine state level monthly review of RNTCP, a national review of the performance of the states is undertaken twice in a year. The national review helps to identify state level problems and suggest remedial measures or actions; deliberate on new initiatives and advocacy.

External Evaluation of the Programme

The program also plans for periodic external assessment of the program by international agencies and partners of the RNTCP, in order to enhance the quality of services provided under the program.

Assessment of Impact

The impact of the program on the TB epidemiology in the community will determine whether TB will be controlled in India. Impact related to TB control activities however, can only be seen after many years of activities. In addition, the outcomes seen can be the result not only of the program activities, but also due to other factors such as improved socioeconomic conditions, severity of the HIV epidemic, etc. The impact indicators should link directly with the Millennium Development Goal (MDG) targets and indicators (Table 49.7). Thus impact indicators, such as annual risk of TB infection and incidence rate, mortality rate due to TB, and levels of drug resistance, etc. are to be measured in the medium and long-term timeframe.

The RNTCP surveillance system collects routine information to measure treatment success and case detection. To evaluate the impact of RNTCP on the incidence of tuberculosis, ARTI survey will be repeated every three to five years. The first such ARTI study was completed in 2003. State-specific ARTI studies are also planned. Estimation of the prevalence and deaths due to tuberculosis in the country will be done directly through field surveys and indirectly by modeling exercises. Such estimations over a period of time will show the long-term impact of the program towards halting and reversing the incidence of TB by 2015.

TABLE 49.7: Millennium development goals

Relevant to TB control are:

Goal 6: To combat HIV/AIDS, malaria and other diseases

Target 8: To have halted by 2015 and begun to reverse the incidence of malaria and other major diseases, including tuberculosis.

Indicators for Target 8 to be used to evaluate the implementation and impact of TB control:

Indicator 23: Between 1990 and 2015, to halve the prevalence and death rates associated with tuberculosis; and

Indicator 24: By 2005, to detect 70% of new smear-positive TB cases arising annually, and to successfully treat 85% of these cases.

TRAINING

RNTCP is implemented through the state health systems. The states contribute significantly to RNTCP in terms of human resources and man-hours. The human resource development policy envisages having at all times adequate numbers of staff at different levels of the health system who have the skills, knowledge and attitude necessary to successfully implement and sustain TB control activities based on the DOTS strategy, including the implementation of new and revised strategies and tools. Development of standardized training material is the responsibility of Central TB Division. A wide range of standardized training material has been made available to the states by Central TB Division emphasizing the need for standardized training throughout the country. Continuous efforts are to be made to ensure good quality of training at all levels.

The states are expected to prepare the projections of training requirement and make an annual training plan, which would be sent to Central TB Division as a part of the States' Annual Action Plan. The training plan takes into account the existing staffing in the state, existing training status and ongoing turnover of staff. The training plan endeavors to have in place maximum numbers of trained staff and plans to minimize delay in training of newly placed staff.

The training is undertaken at different levels. National and central institutes like NTI, Bengaluru; TRC, Chennai; LRS Institute, Delhi; selected medical colleges as well other institutes of eminence undertake training for the state/corporation level officers implementing RNTCP. Trainers from State TB Training and Demonstration Centres, teachers and researchers of the medical colleges and other institutes from all over the country are also trained at the central institutes.

It is planned to have three tiers of training, which will address different needs of the staff providing RNTCP services:

1. *Initial RNTCP training:* This would include induction trainings for all new/replacement staff hitherto untrained in RNTCP. Standard modular training is imparted to all categories of staff responsible for program implementation. It would also include the initial training of NGO personnel, private practitioners, medical college faculty and students and health staff of other sectors.
2. *Retraining:* These trainings would be mainly for individuals who have already received initial RNTCP training, but during supervision activities have been identified to have needs, which require retraining on basic RNTCP activities. The retraining for the individual would be need based and hence staff may need retraining on the complete set of initial training modules, or only on sections related to specific activities.
3. *Updates on new activities and initiatives:* As RNTCP introduces new activities and initiatives, it is important that the field staff members are updated accordingly. These updates could be given during regular program review meetings, such as the monthly district level meeting of the DTO, MO-TCs, STSs and STLSs, or the quarterly state level review meetings.

Standardized training modules for different categories of staff have been developed. The entire training process should be closely monitored by the STO/CMO/DTO/MO-TC, even if she is not directly responsible for each step. The state/district must develop a schedule/calendar for training, select course facilitators, conduct the training, supervise and evaluate the quality. The training should run at least eight hours a day.

Retraining Schedules

During field visits, supervisors should identify staff requiring retraining and the specific areas for the same. Duration of the training will depend on the contents of the training. The maximum duration of training for different categories of staff is listed in Table 49.8.

SPECIAL INITIATIVES

Public-private Mix (PPM)

India has the largest private sector in the world that manages a considerable proportion of tuberculosis cases. The few available studies of the health-seeking behavior of TB symptomatic individuals and patients have shown that more than 50% of patients first approach the private health sector.

Tuberculosis is encountered at all levels and by all types of health services ranging from primary health care services to the highly specialized hospitals in the different health care sectors. Traditionally, control of tuberculosis was considered a responsibility of the public health sector. As a consequence, tuberculosis control programs were designed to be implemented through the available network of public health services. Over the years, the private sector has grown considerably in India. The private health sector in India varies considerably in its

The details of duration of training, size of each batch and veneus are as below:

Initial RNTCP Training

Category	*Duration (working days)*	*Batch size*	*Training material*	*Venue*
STO/STDC staff/District TB officer/ TB-HIV coordinator	14	20	RNTCP MO modules 1-9, STCS/DTCS guidelines, Financial Management manual, Procurement + SDS manual, Monitoring strategy	Central institute
MO-TC/Urban TB coordinator	12	20	RNTCP MO modules 1-9	STDC
MO	5	20	RNTCP MO modules 1-4	District
STS (2+6)	8	12	MPW module, then STS module	STDC
STLS (10+5)	15	6	LT module, then STLS module	STDC
LT	10	8	LT module	District
State drug store Staff/Pharmacist in RNTCP	2	25	MPW module/manual on Std. operating procedures for State drug store	District/TU
MPHS	3	25	MPW module, sections of STS module	District/TU
TB health visitor etc.	2	25	MPW module	TU/PHI
MPW/HA etc.	2	25	MPW module	TU/PHI
Anganwadi worker/midwives/community volunteers, etc.	2	25	DOT provider module	TU/PHI
Community-based DOT providers	1	25	DOT provider module	TU/PHI
Private/NGO/other sector medical practitioners (for PPM module)	6 hr	20	Training module for medical practitioners	DTC/IMA
TO/SA	6	12	STS module	STDC/District
IEC officer	6	Need based	IEC module + MPW module	Central level
Data entry operator	2+2	12	MPW module, then Epicenter training	MPW module and Epicenter at state level
Accountants for district	1	Need based	Manual on financial management and guidelines	State level
Accountant—state level	3	Need based	Financial management manual, DTCS/ STCS guidelines	Central TB division

Initial Training on EQA

Category	*Duration (days)*	*Batch Size*	*Training material*	*Venue*
EQA (Master trainers/ microbiologist)	5	10	EQA manual	Central institute
EQA IRL LTs	5	6	EQA manual	Central institute
EQA STDC Dir/ STO	2	5	EQA manual	Central institute
EQA DTO/MO-TC	2	25	Sections from EQA manual	State level
EQA STLS	2	6	Sections from EQA manual	District level
EQA LTs	1	25	Sections from EQA manual	District level

Initial Training on TB/HIV				
Category	*Duration (days)*	*Batch Size*	*Training material*	*Venue*
TB-HIV master trainers	5	10	TB HIV modules	Central
STO/DTO/MO-DT/MO-TC	2	10	Module for MOs on TB/HIV	State
MO	1	30	Module for MOs on TB/HIV	District
STS/STLS	2	10	Module for STS STLS on TB/HIV	District
DOT provider	1	30	Module for health workers on TB/HIV	TU/PHI

Initial RNTCP Training for Medical College Staff					
Category of	*Type of Duration (in days)*	*Place of training*	*Trainers training*	*Training material*	*staff to be trained*
Medical Staff					
STF chairperson	Concise modular	National institute	Central institute staff	RNTCP –Key facts and concepts	1*
Faculty incharge of RNTCP	MO-TC modular	State-level	STC/STDC staff	1-9 modules	12
TOT's	MO-TC modular	National/ State level	Central institute/ STC/STDC staff	1-9 modules	12
HODs and Senior staff	Concise modular	State level	STC/STDC staff	RNTCP—Key facts and concepts	1
Other faculty members (interested)	MO modules	Medical college	Faculty in-charge of RNTCP	1-4 modules	5
PG students/ Residents/interns/ UG's	Part of Curriculum + sensitization	Medical college	Faculty in-charge of RNTCP	Curriculum	2-3 hrs**
Paramedical Staff					
Nurses	MPW training	Medical college	Faculty incharge of RNTCP	MPW module	2
Pharmacists	MPW training	Medical college	Faculty in charge of RNTCP	MPW module	2
Other paramedical staff	MPW training	Medical college	Faculty in-charge of RNTCP	MPW module	2

*5 days or 12 days modular training for those interested

**Consists of theory classes. Practical training will be imparted during posting to the Chest or Medicine. Departments and the DOTS Cell.

size, composition, and level of organization, types of services delivered and socioeconomic groups served.

Public-private mix includes public-public as well as public-private collaborations. While involving the private sector and other sectors, it is important to have a well-functioning RNTCP in the public sector first. The involvement of other sectors is important to improve the case detection rates under DOTS and successfully treat additional numbers of TB patients. All RNTCP sites, including other sectors will be under regular supervision and monitoring by the programme using the same yardsticks for quality assurance.

TABLE 49.8: The maximum duration of training for different categories of staff

Category	*Maximum duration (days)*	*Venue*
STO/STDC	5	Central institute
DTO/MO-TC	3	STDC
STS	2	STDC
STLS	3	STDC
LT	2	District

TB-HIV (MO)	1	District
TB-HIV (STS/STLS)	1	District

Other Health Providers Involved in PPM

- Government health facilities outside state health departments
- Medical colleges
- Private providers
- Nongovernmental organization
- Corporate sector.

Government Health Facilities Outside State Health Departments

All health establishments under ESI, Railways, CGHS, Defense, Petroleum and Natural Gas, Chemical and Fertilizer, Coal, Steel, Mines, Power, Ports and Prisons come under this group. Most of these departments have been involved in the RNTCP at the central level. State/districts have to ensure that these facilities at the local level are also involved. Directives from the various ministries/departments that control these government health facilities have been made available to the DTOs so that they can facilitate the process.

Private Providers

Private providers are very accessible to patients and can play a key role in TB control. They can be private practitioners or private hospitals/nursing homes practicing modern medicine or other systems of medicine. The first contact of a large proportion of TB patients is a private practitioner. It has been acknowledged that involving private providers helps to improve both case detection and access to standard services under RNTCP. It is vital to have a regular and continuous interaction with the private health care providers to sustain their involvement. To achieve good treatment outcomes, private providers must follow standard RNTCP guidelines. A laboratory owned by a private provider could be considered to be designated as a microscopy center only after it has fulfilled all criteria laid down under RNTCP.

The details of schemes are available in the document “Involvement of Private Practitioners in the RNTCP” published by Central TB Division.

Corporate Sector

Corporate sector includes registered for-profit companies, whether under government or private ownership. They are involved in managing TB in the workplace, either by referring suspects to the RNTCP or, where appropriate, implementing their own workplace programs, especially as DOT centers or DMC-cum DOT centers.

Corporate sector may refer patients to the public sector DMC/DOT center, recognized private sector DMC/DOT center, or may run a DMC or DOT center on its own following the policies and guidelines of RNTCP. RNTCP provides drugs, laboratory consumables, printed material and training to the key staff. A laboratory owned by a corporate sector entity could be designated as a microscopy center only after it has fulfilled all criteria laid down under RNTCP.

Nongovernmental Organizations

For expanding the reach of RNTCP, the Government of India has prepared policies, guidelines and schemes to involve the NGOs. Commodity assistance and grant-in-aid are provided as per the scheme of involvement.

The details of schemes are available in the document "Involvement of NGOs in the RNTCP" published by Central TB Division.

Medical Colleges

Involvement of medical colleges in the RNTCP is a high priority. Continuing success of RNTCP requires involvement of all large providers of health care, including medical colleges. Under RNTCP medical colleges play important roles in service delivery, advocacy, training and operational research.

A National Task Force (NTF) and five Zonal Task Forces (ZTF) have been formed for their effective involvement in RNTCP. Within each zone, nominated medical colleges have been given the responsibility to function as nodal centers. All states, which have medical colleges have formed State Task Forces (STF). In each medical college, there should be a core committee to arrange for training and oversee the functioning of RNTCP in their respective institutions.

The NTF comprises of representatives from 7 nodal medical colleges, CTD, TRC, NTI, LRS and WHO. It has a chairman who is selected on rotational basis from amongst the 7 nodal medical colleges. DDG (TB) is the member-secretary of the NTF. The main task of NTF is to provide leadership and advocacy, coordination, undertake monitoring, lead operational research and support policy development on issues related to the effective involvement of medical colleges in RNTCP.

The ZTF has a representative from the nodal center as chairman, member secretary is the STO of the state where nodal center is located and the members include representatives of the State Task Forces within the zone (1 medical college per state) and STOs of the states within the zone.

The STF has a representative from a medical college in the state as chairman, member secretary is the STO of the state and the members include representatives of each of the medical colleges of the state, on rotation basis if required.

A Medical College Core is formed in each medical college, including least four members, with representatives from the department of medicine, chest medicine, microbiology and community medicine. Coordination of TB control activities is done by DTO.

Management of TB Cases Presenting to a Hospital as Outdoor Patients

RNTCP diagnostic algorithms are to be strictly adhered to by all attending physicians. Diagnosed TB patients should be referred to the local DOTS center in the respective hospital/medical college. Patients coming from the district in which the hospital is situated should be started on DOTS therapy only after the verification of their address. Wherever required RNTCP can provide medical colleges with additional human resource to implement and coordinate the activities with the TU/DTC. One medical officer, one STLS, one LT and one TB health visitor can be provided on contractual basis through the District TB Control Society. Drugs, consumables, etc. will be provided by the DTO.

If patient is required to be referred to another health facility for DOTS, the "referral for treatment" mechanism is to be followed (refer to section on recording and reporting). The respective STS is responsible for tracking of these referral cases. Program review meetings held in the district should be utilized to facilitate the tracking and feedback of referred cases. The receiving treatment facility should honor diagnoses made at the medical college/hospital and must provide feedback to the referring unit.

Management of TB Cases Presenting to a Hospital as Indoor Patients

All indoor patients are to be treated with RNTCP regimens using prolongation pouches, which will be supplied by DTO. The DOTS center of the respective medical college must be informed of the patient's admission at the earliest, to enable transfer of the patient to their respective DOTS center on discharge. On discharge, patients may be given a maximum of three doses (one week drug supply) to cover intervening period prior to their continuation of treatment at their respective DOTS center, hence ensuring no interruption in treatment.

All indoor patients treated under RNTCP, should be registered under the local TU where the medical college is located. The smear conversion and treatment outcome of all the transferred patients should be sent back to the TU of the medical college by the TU where the patient was transferred to.

MULTIDRUG-RESISTANT TUBERCULOSIS AND DOTS PLUS

Multidrug-Resistant TB is a specific form of drug-resistant TB due to bacilli resistant to at least isoniazid and rifampicin, with or without resistance to other anti-TB drugs. The diagnosis of MDR-TB is a laboratory-based diagnosis (from an RNTCP quality assured culture and drug susceptibility testing laboratory) and not a clinical diagnosis. Drug resistance arises due to the improper use of antituberculosis drugs during the treatment of tuberculosis patients. This improper use includes:

- Administration of inadequate treatment regimens by various health care providers
- Wrong treatment categorization due to failure to elicit the history of previous anti-TB treatment by attending physician
- Poor treatment management, when the treatment is not directly observed. Irregular and incomplete treatment due to the lack of effective counseling of patients

Regular chemotherapy under DOTS strategy can prevent the emergence of MDR-TB.

Extent of MDR-TB in India

The prevalence of MDR-TB among new smear-positive cases is relatively low in the country. Studies carried out in six districts during 1999–2002 as per the WHO guidelines on drug-resistance surveillance, showed that 0.5 to 3% of new cases and 12% of previously treated patients were found to harbor MDR-TB bacilli.

Drug Resistance Surveillance

In order to monitor the level of drug resistance in the country, Drug-resistance Surveillance (DRS) is being conducted among both new and previously treated cases in a phased manner in selected states. The national and state-level RNTCP culture and drug susceptibility testing laboratory network will undertake these DRS surveys. The RNTCP designated microscopy centers in each district are assigned the role of identification and enrolment of smear-positive cases for the DRS surveys. RNTCP accredited state level Intermediate reference laboratories perform the culture and Drug Susceptibility Tests (DSTs), with the three national reference laboratories (LRS, NTI and TRC) providing technical support. TRC, which is also a WHO Supranational Reference Laboratory, is responsible for overall quality assurance.

Prevention of MDR-TB

As the management of MDR-TB is very complex, its occurrence must be prevented by the effective implementation of the DOTS strategy.

Proper categorization for the treatment of patients by the attending medical officer, by eliciting any history of previous TB treatment, is very important. The diagnosed patients should be explained why it is essential to know about previous anti-TB treatment, and subsequently the need for them to take their drugs under direct observation. DOT providers should be supervised to ensure DOT provision is as per guidelines. DOTS has been documented to not only prevent the emergence of multidrug-resistance, but also to decrease its prevalence in the community.

Management of MDR-TB

Firstly, it must be remembered that the most important cause of treatment failure is the inability to administer complete and regular treatment to a patient, and not due to drug-resistant bacilli. However, TB cases that continue to be smear-positive at the end of four months or later of an RNTCP Category II treatment may be suspected of having MDR-TB. Only these patients should have a sputum sample collected and sent for culture and DST to an RNTCP quality assured culture and DST laboratory. The STDCs/IRLs are being strengthened to provide such facilities in each state. Diagnosed cases of MDR-TB should be referred to and treated only at a specialized center. Treatment of MDR-TB requires prolonged chemotherapy (24 months), which is also very expensive and toxic. Moreover, the chances of treatment success are moderate.

In 1998, WHO and several partners around the world conceived the DOTS-Plus strategy. DOTS-Plus works as a supplement to the standard DOTS strategy, and is a comprehensive management strategy to address both drug susceptible and MDR-TB, which includes sustained political commitment, diagnosis of MDR-TB through quality assured culture and DST, appropriate treatment strategies that utilize second line drugs under proper management conditions, uninterrupted supply of quality assured second line anti-TB drugs and a standardized

DOTS-Plus recording and reporting system. RNTCP plans to start treatment in 2006 of MDR-TB patients at selected DOTS-Plus sites in the country. By 2010, there will be a network of RNTCP DOTS-Plus sites throughout the country with the facilities to enroll on treatment at least 5,000 MDR-TB patients a year (refer to RNTCP DOTS-Plus guidelines).

INFECTION CONTROL AND HOSPITAL WASTE MANAGEMENT

The Government of India under its Environment Protection Act (1986), passed the Biomedical Waste (Management and Handling) Rules in 1998 and a subsequent amendment followed in 2000. The rules form the legal framework for the collection, segregation, transportation, treatment and disposal of biomedical waste throughout the country. The State Pollution Control Boards (SPCBs) in the states and the Pollution Control Committees (PCCs) in the union territories are monitoring the compliance to the rules in the respective states.

The RNTCP is integrated into the general health system of the states. Waste management is a component of overall facility management of the respective state health system institutions where RNTCP centers are located. Accordingly, the waste generated by RNTCP should not be viewed in isolation, but is to be integrated in the broad framework of the peripheral institutions' waste management practices. The peripheral health institutions would be responsible for the disposal of wastes and reporting to their respective PCBs.

Types of Wastes Generated by the RNTCP

- Human/biological waste (sputum)
- Sharp waste (needles, glass slides, etc.)
- Used blister packs, drug packaging material
- Plastic waste (waste generated from disposable syringes, cups and glasses)
- Laboratory and general waste such as liquid waste, broomsticks and paper waste
- Construction waste (waste generated from civil work activities).

Waste generated under RNTCP will be discarded with the overall waste of the health facility in which services under RNTCP are provided. The staff carrying out RNTCP activities like LTs and DOT providers in PHIs will adopt infection control techniques as detailed in these guidelines and will take action to integrate waste generated under RNTCP into the waste management activities of the concerned PHI. The activities by the PHIs will include organized waste collection, information dissemination, reporting and monitoring of disposal of the waste.

Disposal of Sputum Container with Specimen and Wooden Stick

Sputum containers procured under RNTCP should be made of non-PVC plastic material (polypropylene wherever available).

Step 1: After the smears are examined, remove the lids from all the sputum cups.

Step 2: Put the sputum cups, left over specimen, lids and wooden sticks in the foot operated plastic bucket/ bin with 5% phenol or phenolic compound diluted to 5%. The cups and lids should be fully immersed in the solution. Keep it overnight/ for at least 12 hours.

Step 3: Next day, after at least 12 hours of immersion, drain off the phenol solution into the drain.

Step 4: Take out the sputum cup/lid/wooden sticks and put into a reusable metal or autoclavable plastic container or red bag. The red bag should have a biohazard symbol and be of adequate strength in order to withstand the load of waste. It should be made of non-PVC plastic material.

Step 5: Put this container/bag into the autoclave with other autoclavable biomedical waste and autoclave at 12° C under 15 psi pressure for 15 to 20 minutes. The autoclave shall comply with the standards stipulated in the rules. Under certain circumstances, if autoclaving is not possible, boil such waste in a pressure cooker of approximately 7 liter capacity containing adequate amount of water to submerge the contents and boil for at least 20 minutes using any heating source, electrical or nonelectrical. However the district hospital/CHC/PHC, etc. shall ultimately be expected to make the necessary arrangements to impart autoclaving treatment on regular basis.

Step 6: After adequate cooling, the material can be safely transported to a common waste treatment facility for mutilation/shredding/disposal.

If a Common Waste Treatment Facility (CWTF) is not available in the area, the sputum cups/lids/wooden sticks after autoclaving, can be disposed in a deep burial pit.

LTs and support staff handling biological waste should wear gloves (universal infection control pre-cautions).

Refer to biomedical waste (management and handling) rules and guidelines.

Disposal of Used Syringes/Needles/Broken Vials

Step 1: Immediately after administering the injection, cauterize the needle on site using a suitable needle destroyer/cutter, followed by cutting of the plastic hub of the syringe without detaching the needle from the syringe.

Step 2: Put the cauterized needles, broken vials and ampules into a sturdy puncture proof white translucent plastic/cardboard container.

Step 3: Segregate and store cut plastic syringes in a reusable metal or autoclaveable plastic container/red bag. If a bag is used, its strength should be such that it can withstand the load of waste inside and be made of non-PVC plastic material.

Step 4: Label both the container with biohazard symbol as stipulated in the Schedule III of the Biomedical Waste (Management and Handling) Rules 1998.

Step 5: Put both the containers in the prescribed bag and transport in a dedicated vehicle to the common waste treatment facility for autoclaving, mutilation/shredding, and/or disposal.

Step 6: If a CWTF does not exist, put both sharp container (needles) and metal/plastic container/red bag (syringes) into an autoclave with other BMW, and autoclave at 12° C under 15 psi pressure for 15 to 20 minutes. Under certain circumstances if autoclaving is not possible, boil such waste in water for at least 20 minutes. However, the district hospital/CHC/PHC, etc. should ultimately be expected to make the necessary arrangements to autoclave the waste on regular basis.

Step 7: Dispose off the autoclaved waste as follows:

- Dispose off the needles and broken vials into a sharps pit; and
- Send the syringes for shredding/mutilation or as a landfill in a deep burial pit.

Disposal of Used Slides

Step 1: Place the slides into a puncture-proof container or red bag. The red bag should have a biohazard symbol and should be made of non-PVC plastic material. This bag/sharp container should then be put into an autoclave or pressure cooker for autoclaving/boiling.

Step 2: Dispose of the slides into a pit for sharps.

Under no circumstances should the slides be broken or recycled.

INFORMATION, EDUCATION AND COMMUNICATION

Information, Education and Communication (IEC) is an important component of the RNTCP. Information, education and communication activities under the RNTCP aim to promote a better understanding of TB, especially its diagnosis, treatment and cure; improve the quality of care provided to TB patients; reduce stigma and improve utilization of RNTCP services.

Information, education and communication under RNTCP has the strategic framework for communication that identifies the communication need (objectives), communication players/audience (target groups) and communication tools (channels, activities and materials).

Objectives of IEC under RNTCP

1. *Awareness raising* for behavior change to increase understanding about TB and the use of DOTS services among:
   - The public so that they make use of RNTCP services
   - Health care providers so that they adopt DOTS strategy.
2. *Advocacy* to create, facilitate, develop and forge political, administrative and community-level commitment to TB control in India.
3. *Patient-provider communication and counseling* to help ensure patient compliance with the treatment regimen, to enhance the reputation of a patient friendly service, and to encourage patients and their families to become advocates for the program.

Target Audience

The target audiences for IEC include:

- Patients and community
- Health care providers—both private and public
- Opinion leaders, that includes: Political leaders, state bureaucrats and administrators, PRIs, women groups (mahila mandals), youth clubs, self-help groups (SHGs), professional organizations, etc.

Communication Channels, Activities and Materials

The core messages for the target groups are standardized at central level to ensure that the accuracy of messages is not compromised or diverted from the program's objectives. The messages are tailor-made for each of the target audience. The center provides general outline, and states can develop adaptation using local innovations to reach all possible groups through the appropriate channels, material and activities.

A mix of media options is used to enhance the reach and impact of health communication messages. The use of interpersonal channels, mass media, and nonelectronic media and outdoor media is used to address the large gamut of target audience.

Interpersonal Channels

The value of interpersonal communication has been recognized: Satisfied cured patients are good advocates; interactive meetings are effective in addressing social issues and barriers.

Mass Media

Mass media plays an important role in raising general awareness of TB, efficacy and free availability of DOTS, and advocate support to the program among influential groups and individuals by raising the profile of the program and increasing its visibility amongst opinion leaders. Mass media is important to get information disseminated far and wide.

Nonelectronic and Outdoor Media

Interpersonal approaches are complemented by the options for reaching people in groups or on a collective scale. These include local popular folk media, street plays, use of local markets, mike publicity, puppet shows, activities in schools, wall paintings, hoardings, exhibitions at fairs, etc.

Roles and Responsibilities for IEC Activities at the Center, State and District

The Center takes leadership; states and districts plan and implement IEC activities. Districts draw support from local organizations, PRIs, NGOs, SHGs and there is a two-way flow of information/ideas from and to the center and the state.

Role of Center in IEC

The center has an Advocacy and IEC unit that is assisted by IEC Advisory Group, comprising of honorary members from the centers of excellence in the field of communication, research, media planning and teaching. The center provides:

- Overall leadership for the IEC component
- Procure services of IEC agency and coordinate activities
- Manage the mass media component at national level
- Provide oversight of the national level IEC strategy, assessing capacity for IEC at state level, and providing support where necessary.

Role of the State in IEC

The overall responsibility of planning and implementing IEC activities rest with the state tuberculosis officer. The IEC officer is the nodal person at the state level to assist STO for undertaking following activities:

- Planning of IEC activities for the state, including the district level activities
- Support to districts for planning and implementing IEC activities
- Monitoring and supervision of IEC activities
- Mobilizing support/resources for implementing IEC activities with the involvement of other state/district departments
- Developing material in local languages
- Organizing events for advocacy
- Capacity building of districts for implementing activities for awareness generation and social mobilization

The communication facilitator can be an individual, NGO or an agency to help and assist districts in planning and implementing IEC activities at the subdistrict level. One communicator facilitator is responsible for five to six districts. The responsibility for identifying and appointing communication facilitator is with the state. All districts must be covered by the communication facilitator.

Role of District in IEC

The district is a link between the state and the primary health institutions in the terms of training and dissemination of IEC activities. District is to develop IEC action plan (according to the needs, targets audiences and available communication channels) with the help of IEC officer of the state and is assisted by communication facilitator for the implementation of IEC activities. The district is responsible to:

- Develop plan for IEC activities with sufficient flexibility to allow for local initiatives and variations
- Use local appropriate medium for dissemination of information.
- Seek involvement of local organizations, leaders, *panchayats* and NGOs for IEC
- Organize certain minimum number of activities, such as community meetings, mike publicity, display of posters at each PHI, interaction meetings, wall paintings, puppet shows/street plays/*nautaukis*/*nukkad nataks*, etc.

Monitoring of IEC in RNTCP

Monitoring and supervision of IEC activities is an important aspect. States are responsible for overseeing district and subdistrict level IEC activities. Monitoring indicators for IEC activities have been included in the monitoring strategy for reporting on the activities conducted at the district level, as part of PMR report. Supervisory IEC checklist is used for overseeing that activities have been undertaken as planned.

Treatment of Tuberculosis in Special Situations

Rajendra Prasad

INTRODUCTION

Treatment of tuberculosis poses a difficult clinical problem in special situations like pregnancy, renal insufficiency and liver diseases. There are various concerns regarding dosage, toxicity and the method of administration of drugs. Prior to discussing the specific issues, it is important to know the important pharmacokinetic characteristics of individual antitubercular drugs.

PHARMACOKINETICS OF ANTITUBERCULAR DRUGS

Some antituberculosis drugs are metabolized in liver; while others are excreted either unchanged or in metabolized form, by the renal route. Their secretion in milk and ability to cross placenta is important in the situations of lactation and pregnancy, where there is concern of safety and morbidity of the baby.

Isoniazid is rapidly absorbed from gut, metabolized in liver by acetylation and the inactive metabolites are excreted in urine within 24 hours. Its half-life varies from one group of population to other, depending upon hepatic acetylation. Half-life is less than one hour in rapid acetylators, and more than three hours in slow acetylators. It is secreted in milk, but the amount is not sufficient to provide antitubercular chemoprophylaxis to infant. It is safe in pregnancy, but the risk of hepatitis may be increased in the postpartum period.[1] Rifampicin is rapidly absorbed and widely distributed to tissues and bound to plasma protein. Its absorption is reduced if given with food (not of clinical significance), or if given along with Para-aminosalicylic Acid (PAS). It is extensively recycled by enterohepatic circulation, and the metabolites formed by deacetylation are excreted in feces. It is found to be safe in pregnancy, with some risk of postnatal hemorrhage.

Ethambutol is rapidly absorbed from the gut. It is predominantly excreted in urine in an unchanged form or an inactive hepatic metabolite (80%).[2] Only 20% is excreted in feces as unchanged drug.[3] Ethambutol is found to be safe in pregnancy and liver disease. Pyrazinamide is also rapidly absorbed from gut, metabolized in liver to metabolites, pyrazinoic acid and 5-hydroxypyrazinoic acid, which are excreted largely by the renal route.[4] Its safety in pregnancy is somewhat controversial.[4] Streptomycin is largely concentrated in the extracellular fluid. In pregnant women, it may interfere with development of fetal ear.[5] Plasma half-life is prolonged in the newborn, elderly patients and in patients with renal failure. It is excreted unchanged in urine. Pharmacokinetics of amikacin, kanamycin or capreomycin are similar to those of streptomycin, and found unsafe in pregnancy, where they may cause fetal nephrotoxicity or congenital deafness.[5] They are considered safe in liver disease.

Ethionamide and prothionamide are toxic to liver and teratogenic in pregnant animals. Their safety in liver disease and pregnancy is doubtful, and should not be used in pregnant women. They are considered relatively safe in mild renal disease. Cycloserine is about one-third metabolized, and the rest excreted in urine. It is not safe in patients with renal failure. In alcoholics, it may lead to seizures. It crosses the placenta in pregnancy, and its safety in this situation is not yet established. PAS is not safe in renal failure. About 80% of drug is excreted in urine, and it should be avoided in severe renal insufficiency, where it may aggravate the problem of metabolic acidosis.[6] Old preparation of PAS interacted with rifampicin absorption, but new preparation of granules has no interaction with it.[7] There are no studies on its safety, in pregnant women, but it has been safely used in pregnancy in the past. Fluoroquinolones are also not found safe, as they are found to inhibit the growing cartilages of bones in animal studies. About 80% of levofloxacin is cleared by kidney, its dose adjustment is recommended in the cases of renal insufficiency.[8] These drugs, except ciprofloxacin, which is metabolized in liver are generally safe in the cases of liver disease.

TREATMENT OF TUBERCULOSIS IN PREGNANCY AND LACTATION

Isoniazid is considered safe in pregnancy, except for some chance of postpartum hepatitis.[1] The American Thoracic Society (ATS) recommends supplementation with pyridoxine during pregnancy (25 mg/day).[4] Use of rifampicin and ethambutol is safe in pregnancy. Data regarding other rifamycins (rifabutin and rifapentine) is insufficient, and thus, they should be cautiously used. Safety regarding pyrazinamide cannot be assured, but when used for six months regimen, the benefits may outweigh the possible risk.[3]

Streptomycin may cause congenital deafness, as this drug interferes with the development of ear.[5] Other injectables, like amikacin, kanamycin and capreomycin having pharmacokinetics similar to streptomycin, may also cause fetal nephrotoxicity and ototoxicity.[5] One study reported that 17% of babies born to ladies who received streptomycin during pregnancy, developed hearing loss.[9] Ethionamide and prothionamide are contraindicated in pregnancy, as they are found teratogenic in animal studies. Cycloserine crosses placenta, and since, its safety in pregnancy is not established, it should be avoided, and used only if no other suitable alternatives are available.[5] PAS has been used safely in pregnancy in past. Since, no well designed study has been done to ascertain its safety in pregnancy, it should be used only in the absence of any other alternative. Fluoroquinolones being toxic and inhibitor of growing cartilage in animals, should be avoided in pregnancy.[9]

Treatment of tuberculosis in a pregnant woman is far less hazardous than leaving the disease untreated, both with regard to the baby and the mother. Tuberculosis in pregnancy may lead to the birth of an underweight infant or to congenital tuberculosis.[10] Risk of miscarriage is much higher in active tuberculosis than the risk from the drug treatment, so standard treatment should be given. Treatment regimen for drug sensitive tuberculosis should include at least the three first line drugs—rifampicin, isoniazid and ethambutol. Streptomycin should not be used. Opinion regarding the use of pyrazinamide is divided, but World Health Organization (WHO) and International Union Against Tuberculosis and Lung Disease (IUATLD) recommend its use.[3] ATS does not confidently advocate its use.[4] According to WHO, six months regimen based upon isoniazid, rifampicin and pyrazinamide should be used whenever possible, and ethambutol should be used only if a fourth drug is needed during the initial phase.[3] Contrary to this, ATS recommends that pyrazinamide should better be avoided in pregnancy, because of the lack of sufficient data for its safety.[4] If pyrazinamide is not used, duration of treatment should be prolonged to nine months. Although, isoniazid, rifampicin and ethambutol cross the placenta, they are not found to be teratogenic.[9]

Women taking first line antituberculosis drugs should not be asked for termination of pregnancy, while those on reserve drugs should be counseled for possible adverse effects. Breastfeeding should not be discouraged, as the amount of drugs secreted in milk is insufficient to cause any toxic or therapeutic effect. Supplemental pyridoxine is recommended for both the nursing mother and her infant, even if no isoniazid is being given to the infant. All antituberculosis drugs can be used during lactation, except fluoroquinolones.[9] Baby of a woman who has taken rifampicin during pregnancy should receive vitamin K at birth, to avoid the risk of postnatal hemorrhage.[3] Rifampicin may induce metabolism of vitamin K and hamper hepatic synthesis of vitamin K dependent coagulation factors.

Women taking oral hormonal contraceptives should be counseled for possible contraceptive failure and occurrence of pregnancy. This is especially so in women on rifampicin containing antitubercular treatment regimen, because of the induction of metabolism of contraceptive drug by rifampicin.[11,12] Such women should be advised to use non hormonal contraceptive measures during, and for one month after treatment with rifampicin containing regimen.[12,13]

TREATMENT OF TUBERCULOSIS IN RENAL INSUFFICIENCY

Treatment of tuberculosis in renal insufficiency poses a difficult clinical problem because various antituberculosis medications are cleared by kidney. On one hand, it raises the concern of drug-induced toxicity due to impaired excretion by the diseased kidney, while on the other hand, it raises the concern of under treatment of tuberculosis. In later situation, adequate peak serum concentration is usually low, and not of therapeutic use.[4] Another issue of concern is the achievement of the therapeutic level of antituberculosis drugs in patients with end stage renal disease, undergoing hemodialysis, which may alter/lower the serum drug levels.

The British Thoracic Society advocates dose reduction for drugs, which are excreted by the renal route, while the American Thoracic Society prefers increasing the dosing interval instead of decreasing the dose.[4,11] Administration of drugs,which are excreted by kidneys should be changed by increasing the dosing interval, if creatinine clearance falls below 30 ml/min. There is paucity of data to guide the dosing recommendation if creatinine clearance is above 30 ml/min, when standard doses should be prescribed.[4] Rifampicin and isoniazid are eliminated by liver, and they could be given in the usual dosages.[14] Population with slow hepatic acetylation of isoniazid, could be given supplemental pyridoxine to prevent peripheral neuropathy.

Alteration in dose of ethambutol, which is 80% excreted by kidney,[2] should be made if creatinine clearance falls below 70 ml/min,[4] to the lowest possible dose, but if it falls below 30 ml/min, it should be given intermittently as three times a week in dose of 15 to 20 mg/kg body wt.[4] Pyrazinamide is metabolized in liver, but its metabolites, pyrazinoic acid and 5-hydroxypyrazinoic acid are excreted by kidneys.[15,16] Thus, the drug should be given three times a week, in dose of 25 to 35 mg/kg body weight, to avoid toxicity, if creatinine clearance falls below 30 ml/min.[4] Apart from this, the risk of developing hyperuricemia with pyrazinamide is increased in the cases of renal insufficiency.

Since, streptomycin is predominantly excreted by the renal route, and removed by hemodialysis to a significant extent (about 40%), it should be administered three times a week in dose of 12 to 15 mg/kg body weight in patients of renal insufficiency with creatinine clearance below 30 ml/min, and those on hemodialysis.[4,17] Since, pharmacokinetics of other aminoglycosides are similar to those of streptomycin, they need similar modifications of dosages.[4] Renal clearance of fluoroquinolones varies from drug to drug. It is greater for levofloxacin than moxifloxacin.[18] Dose adjustment for fluoroquinolones is recommended if creatinine clearance is less than 30 ml/min (750 to 1,000 mg, three times a week).[4]

Ethionamide need no or little alteration of administration as it is not excreted by kidney.[19] If creatinine clearance is less than 30 ml/min, dose of ethionamide should be reduced to 250 to 500 mg/day.[4] Dose of cycloserine should be modified if creatinine clearance falls below 30 ml/min or patient is on hemodialysis. It should be changed to 500 mg thrice a week or 250 mg daily.[4] Evidence for safety of 250 mg daily dose of cycloserine is not yet established with regard to neuropathy; 500 mg three times a week, is preferred. Serum concentrations of drug should be monitored. PAS is not safe in renal disease and should only be given if no other alternative is available, as it may aggravate metabolic acidosis.[6] It should be given at a dose of 4 gm/dose, twice daily. Thioacetazone, also excreted in urine, should not be given to patients with renal disease.[20]

Hemodialysis may remove the drug before its therapeutic effect is established. If the drug is given sufficiently before hemodialysis, far less drug is likely to be removed. It therefore, gets time to be distributed throughout the body. Administration of drug after hemodialysis, will avoid the premature removal of drug. This may also facilitate the Directly Observed Treatment Short-course (DOTS) strategy indirectly.[4] Premature removal of second line drugs, by hemodialysis, may further aggravate the problem of drug resistance by exposing the tubercle bacillus to subtherapeutic drug concentrations. Rifampicin, isoniazid and ethambutol are removed to a much less by hemodialysis, but pyrazinamide is removed to a significant extent.[15] Thus, supplemental dosing is not needed with isoniazid, rifampicin and ethambutol, in patients of end stage renal disease, undergoing hemodialysis. Similar to streptomycin, about 40% of drugs like kanamycin, amikacin and capreomycin are removed from blood, if they are given just before hemodialysis.[17] Fluoroquinolone and ethionamide are not cleared by hemodialysis and thus, their dose need not be altered in this situation.[18, 19] Usually, hemodialysis does not pose significant problem, if drugs are given after the procedure.

Ideally, it is important to monitor serum concentrations of drugs in persons with renal failure who are taking aminoglycosides, cycloserine or ethambutol to provide effective therapeutic drug concentrations and also to minimize dose related toxicity. Patients with renal failure may have other comorbid conditions, like diabetes mellitus and gastroparesis, which may further complicate the pharmacokinetics of drugs.[21] Presently, there is no data to guide administration of antituberculosis drugs in patients undergoing peritoneal dialysis. For this subset of patients, recommendations as of hemodialysis, are applicable. The safest regimen that is being advised in patients diagnosed as the new cases of tuberculosis with renal insufficiency, is rifampicin, isoniazid and pyrazinamide for two months followed by rifampicin and isoniazid for next four months.[20]

TREATMENT OF TUBERCULOSIS IN LIVER DISEASE

Treatment of tuberculosis with deranged liver functions presents with two major clinical scenes. First is the issue of antitubercular drug-induced hepatotoxicity and second, use of antitubercular drugs in persons with pre-existing liver disease. Various antitubercular drugs are potentially hepatotoxic, and administration of these drugs may aggravate liver disease, in a patient with compromised liver function. Drugs like ethambutol, streptomycin, kanamycin, amikacin and capreomycin are safe in liver disease as they are neither significantly metabolized, nor toxic to liver. [4]

Drug-induced Hepatotoxicity

It is found that, the period of latency between the start of drug regimen and the occurrence of drug-induced hepatitis is usually four to nine days.[22] It must be known that, about 10 to 30% of patients receiving antituberculosis therapy may normally have the transient rise of bilirubin and liver enzymes [Serum Glutaryl Pyruvate Transaminase (SGPT) and Serum Glutaryl Oxalate Transaminase (SGOT)], to about one to three times the normal, during the first-two months of therapy. The levels generally come down on continuation of treatment. It is of interest to note that about 10% of patients, who develop mild transaminase elevation (i.e. 1 to 2% of all treated adults), may have severe hepatitis and liver failure until the drug is discontinued. This clinical condition has the case fatality of approximately 10%. Drug-induced hepatitis is diagnosed, when serum level of SGPT or SGOT rises more than 150 IU/lit on more than three occasions, or greater than 250 IU/lit on one occasion, along with values of serum bilirubin of more than 34.2 micromol/ lit (2 mg%).[22]

The incidence of isoniazid induced, clinical hepatitis is lesser than was previously thought. Hepatitis occurs in 0.6% patients, if isoniazid is given alone, but it is 1.6% if given with drugs, other than rifampicin.[23] With rifampicin, the incidence of hepatitis is 2.7%. Risk of drug-induced hepatitis, increases with age, and it is 2% in persons aged 50 to 64 years. Rate of fatal hepatitis is 0.023%. If it is given to patient with preexisting liver disease, it may accumulate in body and further increase the risk of drug-induced hepatitis.[4] Frequent monitoring of serum level of hepatic transaminases is indicated in this clinical setting.[3]

Patients with alcoholic liver disease, are at increased risk of peripheral neuropathy, and should be given pyridoxine prophylactically at a dose of 10 mg daily.[3] Rifampicin may cause normal transient hyperbilirubinemia in 0.6% patients. Incidence of hepatitis is 2.7% if it is given with isoniazid, and it is 1.1%, if given with a drug other than isoniazid.[23] Clearance of rifampicin, may be impaired, causing serum levels to rise, if it is given to a patient with pre-existing liver disease. Careful monitoring of liver functions is indicated in such patients.[3]

All the three first-line drugs isoniazid, rifampicin and pyrazinamide are associated with hepatotoxicity. Of the three, rifampicin is least likely to cause hepatocellular damage, although it is associated with cholestatic jaundice. Pyrazinamide is the most hepatotoxic of the three first-line drugs. Among the second-line drugs, ethionamide, protionamide and PAS can also be hepatotoxic, although less so than any of the first-line drugs. Hepatitis occurs rarely with the fluoroquinolones.[24]

Chemical structure of ethionamide is similar to that of isoniazid. It can cause liver toxicity in about 2% patients, and should be cautiously used in the presence of pre-existing liver disease. PAS may cause clinical hepatitis in 0.3% cases. Since, pharmacokinetics of PAS are not significantly altered in liver disease, it could be used in usual doses and usual regimen.[6] Cycloserine can be safely used in liver disease, except in the case of alcohol related hepatitis, where it increases the risk of seizures.[5] Thioacetazone is hepatotoxic, and it should be avoided. Fluoroquinolones except ciprofloxacin, are safe for use in liver disease.[13]

Advanced age, female sex, poor nutritional status, preexisting liver disease, chronic alcoholism, Hepatitis B carrier state and slow acetylator status are considered risk factors for antitubercular drug-induced hepatitis.[22,,24-26] Several studies have observed relation between serum markers for viral hepatitis and antituberculosis drug-induced hepatitis. It has been observed that viral hepatitis complicates treatment more frequently with regimen containing both rifampicin and isoniazid, than with regimen having only one or none of them.[22, 25]

It is often difficult to find the culprit drug, in a multidrug regimen, causing drug-induced hepatitis. The rise in serum transaminase activity within 15 days of starting regimen is usually attributed to rifampicin, but if it occurs after one month, it is usually attributed to pyrazinamide.[25] Whether the toxicity occurs due to their additive effect, synergistic effect, hypersensitivity phenomenon or direct effect is not known. The Joint Tuberculosis Committee of the British Thoracic Society recommends that liver functions should be monitored weekly during the first-two weeks, and then at two weekly interval, in patients who have pre-existing liver disease.[27] Recommendation for the frequency of monitoring liver functions, in patients with no known risk factors is not clear.

If a patient on antituberculosis therapy develops mild and transient elevation of serum bilirubin or liver enzymes, treatment need not be stopped. They usually come down during the course of treatment. If patient develops hepatitis related symptoms with the significant elevation of bilirubin and liver enzymes, treatment should be stopped and viral hepatitis should be ruled out by serology.[27] Drugs should be gradually reintroduced one by one starting from less hepatotoxic drug first, after liver functions come down to normal, with close monitoring for deterioration.

Antituberculosis Treatment with Pre-existing Liver Disease

In case of stable liver disease, all antituberculosis drugs can be used, with close observation for liver functions. In patients with unstable or advanced liver disease, liver function tests should be done at the start of treatment. If the serum SGPT level is more than three times normal before the initiation of treatment, lesser hepatotoxic regimens should be considered. The alternate regimens are devised on the premise that the more unstable or severe the liver disease is, the fewer the hepatotoxic drugs employed. Possible regimens include those that employ two hepatotoxic drugs (rather than three in the standard regimen): (a) Nine months of isoniazid and rifampicin, plus ethambutol (until or unless isoniazid susceptibility is documented); or (b) Two months of isoniazid, rifampicin, streptomycin and ethambutol, followed by six months of isoniazid and rifampicin; or (c) Six to nine months of rifampicin, pyrazinamide and ethambutol is administered.[28]

When the liver disease is too serious to permit use of more than one hepatotoxic drug, a regimen comprising two months of isoniazid, ethambutol and streptomycin, followed by ten months of isoniazid and ethambutol is preferred.[28] In the extreme case of fulminant hepatic failure where antitubercular treatment is indispensable, a regimen devoid of any hepatotoxic drug is prescribed; such as 18–24 months of streptomycin, ethambutol and a fluoroquinolone.[28]

In conclusion, different options are used for the treatment of tuberculosis with deranged liver functions; mild derangements in liver enzymes require merely a close watch on the liver function without modifying the regimen while the progressively declining hepatic reserves prohibit the use of any potential hepatotoxic drug requiring a substantial revision of the antitubercular regimen. Expert consultation is hence desirable in treating patients with advanced liver disease.[28]

Tuberculosis and Human Immunodeficiency Virus Infection

SK Jindal

INTRODUCTION

The Acquired Immunodeficiency Syndrome (AIDS) recognized first in 1980–81 in patients diagnosed with Kaposi's sarcoma and Pneumocystis Carinii Pneumonia (PCP), was attributed to the Human Immunodeficiency Virus (HIV) infection. In a short span of a little over a quarter of a century, the disease has made an enormously devastating impact on the global health care infrastructure. In particular, it has worsened the scene of Tuberculosis (TB) all over the world by adversely influencing its epidemiology, clinical outcomes and treatment-strategies, forcing major changes in the control programs.

Both TB and HIV infections are deadlier together, TB causing one quarter of AIDS-related deaths and HIV infecting at least 15% of patients with TB worldwide.[1] The HIV and TB coinfection has come to be known as a deadly duet, a difficult and frequently fatal combination. TB is the most common opportunistic infection in HIV infected persons in several countries, including in India.[2]

EPIDEMIOLOGY

There are estimated 33.2 million persons infected with HIV, of whom about one-third are also infected with *Mycobacterium tuberculosis* (*M. tb*).[3] The TB incidence in HIV infected persons is about 100 fold more than in the general population. According to the WHO/UNAIDS estimates, up to half of the patients with HIV or AIDS develop TB. The estimated number of new cases of TB in HIV infected individuals rose by almost 100% from nearly 0.7 million in 2006 to 1.4 million in 2008, TB also accounted for 26% of AIDS related deaths.[2-4]

Most of the increase in HIV related TB, as well as the deaths from TB in patients of AIDS occurred in the developing countries. HIV infection was an important factor for the resurgence of TB in the United States and Europe around the turn of the millennium. However, the effective steps undertaken by these countries have successfully contained the dual epidemic. A recent assessment of population based TB rates among HIV infected persons in the New York City (from 2001 to 2005) was made from the city's TB and HIV/AIDS surveillance registries; TB in HIV infected persons was 16 times the TB rate of a "non-HIV" population.[5] However, the decline was primarily limited to the US born and not the foreign born HIV infected population.[5] A majority of foreign born persons are likely to come from the developing countries, clearly demonstrating the disparities in the prevalence of HIV-TB coinfection.

Although the HIV-TB scene in several countries is dismal, this may not be so, in the India. This is partly attributed to the successful implementation of the Revised National Tuberculosis Control Programme (RNTCP) and the strategy of Directly Observed Therapy Short-course (DOTS). There is an effective HIV-TB coordination undertaken under RNTCP. Moreover, the estimated number of people living with HIV/AIDS (PLWHA) in India has been revised to 2.5 million people from the earlier reported figure of 5.7 million.[6,7] The revised figures are also likely to reflect the reduced HIV-TB burden.

The HIV epidemic has greatly upset the TB control programs of several countries. Tuberculosis has proven to be difficult to control in high HIV prevalence zones.[8]

Considering the observation that almost 80% of persons with TB have HIV infection in some African countries, it has been strongly felt that an integrated preventive strategy is essential for both TB and HIV infection.[8-10] Enhanced implementation of TB-HIV collaborative activities and a focused research agenda are critical to the success of control programs, especially in the resource-limited countries.[10,11]

PATHOGENESIS

The lifetime risk of active TB in HIV infected individuals is as high as 30 to 50% compared to 5 to 10% risk of active disease in tuberculin positive, non-HIV infected individuals.[12] In India, it is estimated that 50 to 60% of HIV infected persons will develop TB during their lifetime.[13] HIV induced immunosuppression is the most important risk factor for an increased occurrence of TB. While HIV infection is responsible for the resurgence of TB in the West, it is an important cause of an increased morbidity and mortality in the high TB burden developing countries.

There are several immunological defects in HIV infection, which predispose to TB and encourage HIV-TB coinfection (Table 51.1). HIV infection is primarily responsible for impaired Cell-Mediated Immunity (CMI) by causing a decline in the number and function of CD4+ subset of T-cells.[14] There is a diminished recruitment and activation of CD4 cells. The other components of CMI, such as the macrophages and peripheral blood monocytes are also affected and their function impaired. There is resultant reduced production and activation of mediators, such as the cytokines and lymphokines. HIV infection also results in an increased secretion of TH-2 (IL4 and IL10) cytokines that are antagonist to (IL-2, IL12 and IFNγ) cytokines, which mediate the immunity to tubercle bacilli. In addition, there is a failure of macrophage differentiation to epithelioid cells and formation of Langham cells. This global impairment of cellular arm of immunity seriously reduces the immune defenses against several intracellular and other pathogens, especially the mycobacteria.

TABLE 51.1: Immune alterations/defects in HIV infection, which predispose to TB

1. CD4+ T cell: Decline in number
    - depletion
    - Functional impairment
    - Diminished recruitment and activation
2. Impairment of macrophages and peripheral blood monocytes.
3. Increased secretion of TH-2 cytokines (IL-4 and IL-10) by the mono nuclear cells.
4. Failure of macrophage differentiation (to epithelioid cells)
5. Lack of formation of Langhans giant cells
6. Enhanced HIV replication by:
    - Increased production of TNF- α by *M. tb*
    - MTB and its cell wall components
    - Beta chemokine monocyte chemotactic protein
    - Down regulation of chemokines

Factors additional to or other than CD4 T-cell decline and impairment may also partly account for increased predisposition to TB.[15] *Mycobacterium tuberculosis* infection may induce nuclear factor binding to the NF-KB sequences in the HIV replication. The increased HIV replication by *M. tb* sets a vicious cycle in both promoting growth of each other and therefore, the continuing damage to the host cells. Tuberculosis can occur in patients with HIV infection at all levels, but the type, severity and manifestations depend on the CD4 T-lymphocyte counts. The greater the degree of immunosuppression and the lower the CD4 counts, more likely the atypical presentation.

As the immunosuppression progresses, there occurs increased likelihood of infection by atypical and opportunistic mycobacteria and decreased tuberculin reactivity. Granuloma formation is impaired while the lesions show high content of intracellular organisms. The absence of inflammatory cellular response in the presence of a large number of organisms and "naked necrosis" is sometimes referred to as "nonreactive" form of TB.

CLINICAL EFFECTS OF HIV ON TUBERCULOSIS (TABLE 51.2)

Increased Susceptibility

HIV infected persons acquire TB infection more frequently when exposed to *M. tb*.[16] This phenomenon of increased susceptibility is now supported by the reports of explosive outbreaks of TB among HIV infected persons exposed to a patient with infectious tuberculosis, 11 of 30 (37%) residents who were exposed to a patient with infectious TB living in a residential care facility for HIV infected persons in San Francisco, developed TB within 120 days.[17] It was also shown with the help of Restriction Fragment Length Polymorphism (RFLP) analysis that all 11 of those patients had TB caused by the same strain of *M. tb* supporting the single source of origin of infection.

Infectivity

On an individual basis, HIV infected patients with TB are less likely infectious than those without HIV infection.

TABLE 51.2: Clinical effects of HIV infection on TB

- i. Increased susceptibility to TB
- ii. Increase infectivity?
- iii. Reactivation of latent TB
- iv. Clinical manifestations:
  - – "Typical"- pulmonary
  - – "Atypical" pulmonary/Pleural TB
  - – Extrapulmonary – Lymphadenopathy, meningitis, brain abscess, pericarditis, peritonitis, liver abscess (and others).
- v. Drug resistant TB
  - – Multidrug resistance
  - – Extensive drug resistance
  - Poor treatment response
  - Higher mortality rates
- vi. Tuberculin skin sensitivity
  - – Diminished or absent

There are several possible reasons, for example, TB in HIV infected patients is generally noninfectious extrapulmonary or paucibacillary pulmonary with fewer bacilli in the sputum.[18] This however, is not always true. There are other studies, which report the opposite findings.[19] However, in HIV infected communities with HIV-TB coinfection, the number of persons with communicable TB keeps on multiplying with increased transmission to other people regardless of their HIV status.[20]

Reactivation of Latent Infection

Human immunodeficiency virus increases the rate of TB reactivation in a previously infected patient (latent TB). The annual risk of developing TB in a PLWHA, coinfected with *M. tb* is 5% to 15%.[21,22] Both reactivation of previous infection and exogenous reinfection are reported to occur in these patients.[23] Possibly, reactivation is the more likely mechanism in low prevalence Western countries with a lower level of exposure to patients with active disease, although the occurrence of new infection has been also shown with the help of RFLP analysis.[20,24,25] New infections from different strains are however, common in the high TB-burden countries.[26]

A recent study from Malawi explored differences in "clustering" (i.e. sharing of identical *M. tb* strains) in patients clustered by prior *M. tb* infection and HIV status. In HIV positive TB cases, clustering was similar in patients with previous *M. tb* infection and without prior infection.[26] It was thus concluded that the HIV infection also increased the risk of reinfection following exposure in patients with latent TB.[26]

Clinical Manifestations

The clinical features of TB in HIV infected patients depend upon the severity of immunosuppression.[27-30] (Table 51.2). The presentation in early HIV disease is almost similar to that observed in otherwise healthy individuals, in whom pulmonary disease with focal infiltration and cavities is more common, while extrapulmonary manifestation and other atypical features are common when the CD4+ counts are less than 200/mm^3.[4,31,32]

"Typical" pulmonary disease presenting with fever and other constitutional symptoms, cough, expectoration and hemoptysis is not uncommon. Several of these patients are diagnosed to have HIV coinfection on only serological tests. On the other hand, several series have emphasized the presence of frequently disseminated disease with extrapulmonary organ involvement.[27,28,33-35] Lymphadenopathy, including mediastinal, hilar and peripheral is commonly described. Relatively uncommon sites for TB, such as the gastrointestinal, genitourinary, cardiac and central nervous system are more often involved in the presence of HIV infection. Disseminated disease is a common presentation in childhood TB.[35] Night sweats, fatigue, diarrhea and hepatosplenomegaly are other common features in these patients.[36]

Both pleural and parenchymal pulmonary involvements are common in HIV-TB coinfection.[37] Pleural fluid in the presence of HIV infection may more often show the presence of Acid-Fast Bacilli (AFB), on both smear and culture examinations.[38] These mycobacteria may also show the presence of drug resistance, similar to that seen in parenchymal TB.[38,39]

Occurrence of TB in an HIV infected patient in the previous two years is also used for HIV/AIDS staging. It is categorized as clinical stage 3 disease in case of pulmonary and stage 4 in case of extrapulmonary TB.[40] Systemic manifestations include the presence of associated/complicating illnesses attributed to HIV immunosuppression. Recurrent pneumonias, diarrhea, herpes zoster infection and mucosal (oral/genital/gastrointestinal) ulcerations are common. Weight loss of more than 10 kg or more than 20% of original weight loss is an important AIDS defining criterion.

Drug Resistance

Emergence of Multidrug Resistance (MDR) and Extensive Drug Resistance (XDR) TB strains is a serious challenge all over the world[41] (see Chapter 48). There occur around 490,000 cases of MDR-TB with more than 110,000 deaths and 40,000 XDR-TB cases every year as per the WHO estimates.[42] It is further assessed that only 7% of MDR-TB were identified and reported to WHO, of whom only one-fifth were noted according to WHO standards.[41] Although there is no real evidence to suggest an increased predisposition, there exists a theoretical association in view of the increased susceptibility and higher risk of treatment failure in HIV infected patients to develop MDR-TB.[43] There is little doubt that the prevalence of both MDR-TB and XDR-TB have substantially increased, following the HIV epidemic.[44] The threat of an "untreatable TB," i.e. XDR-TB has particularly posed a global concern.[44]

The clinical and radiological manifestations of MDR-TB in HIV infected individuals are generally similar to those of MDR-TB in non-HIV infected patients, but pose greater problems of symptom and severity control due to poor treatment with pulmonary cavitary and/or disseminated disease. High mortality rates are reported in MDR-TB patients with than in those without HIV infection.[45] Transmission rate of MDR-TB in HIV infection is also high. Ninety-eight percent mortality was reported in 53 patients of XDR-TB, of whom 44 were HIV infected with a median survival of only 16 days after the diagnosis was established.[46]

DIAGNOSIS

Diagnosis of TB in HIV infected patients is established on the same lines and methods as in non-HIV infected patients (see Chapter 40). However, diagnosis in the presence of HIV infection is somewhat difficult in view of the difficulties of AFB demonstration in cases of extrapulmonary and noncavitary pulmonary TB. There is lesser likelihood of sputum smear and culture positivity in the presence of HIV infection, this observation is not corroborated in some of the studies.[47,29] The lesser sensitivity and specificity of sputum microscopy is attributed to the presence of fewer bacilli in the sputum because of the diminished chances of cavitation from a disregulated cellular response and due to increased incidence of infection with nontuberculous mycobacteria.[48,49] Culture of *M. tb* from sputum and/or other pathological specimens and secretions is diagnostic of TB. The practical utility of mycobacterial culture is however limited, especially in control programs.

Radiological diagnosis of TB is nonspecific. This is especially so, in the presence of HIV coinfection when the chest X-ray findings are generally atypical.[50] Moreover, the chest radiology is frequently negative in extrapulmonary manifestations of TB. More importantly, one relies on cytological and/or histopathological examination for the demonstration of caseation, granuloma formation (which are ill formed and rare) and AFB. Investigational procedures, such as fine needle aspiration biopsy, pleural fluid aspiration, lumbar puncture, forceps biopsy, bronchoscopic or trans-bronchial biopsy and other methods are used to obtain the appropriate specimen for these examinations.

Interpretation of the Tuberculin Skin Test (TST) in the presence of HIV infection for the diagnosis of TB is somewhat difficult, especially in the high TB prevalence countries. A positive TST is considered as suggestive of TB-infection or latent TB in any individual, more so, in the presence of HIV infection in whom the test sensitivity is further reduced. In countries, such as India, where there is presence of TB infection diagnosed by a positive TST in up to 40 to 50% of normal healthy population, the positive test cannot be considered as an indication for the treatment.

In the presence of immunosuppression due to HIV infection, the positivity of TST can be considered as more valuable. The probability of positive TST in these patients is significantly low,[51] therefore, a positive test may "strongly" suggest TB. It is for this reason that the cutoff values for positivity for TST are lower for HIV infected patients.[52,53] However, a lower "cutoff" may not necessarily differentiate between "infection" and "disease". In a retrospective medical record database review (1988 to 2007), the administration of TSTs to newly diagnosed HIV patients was inconsistent and different according to the country of birth, among other factors, resulting in "missed opportunities for TB prevention." [54]

The Interferon-Gamma Release Assays (IGRA) tests are now employed for the detection of latent TB with the help of QuantiFERON-TB Gold test and T-Spot tests.[55] These tests like TST are unable to differentiate between TB infection and active TB disease. We do not have figures on positive IGRA in otherwise healthy people, but the interpretation is somewhat similar to that of TST.[56] The updated guidelines for using IGRA in the United States suggest their use as aids in diagnosing TB infection in different populations.[57] A lot of work is still required before a recommendation of their use to guide treatment in India can be made, including in the presence of HIV infection.

MANAGEMENT

The greatest challenge in managing HIV-TB coinfection lies in the simultaneous treatment of both the infections and frequently of other concomitant opportunistic

TABLE 51.3: Important issues in the treatment of TB-HIV coinfection

1. Antitubercular therapy
   - i. Choice of drugs
   - ii. Choice of regimen
   - iii. Optimum duration of therapy
   - iv. Directly observed therapy short course (DOTS)
   - v. Treatment for MDR-TB and XDR-TB
   - vi. Prevention of recurrence of TB
2. Anti-HIV (Retroviral) therapy
   - i. Polypharmacotherapy
   - ii. Overlapping side effects of drugs

infections. The basic principles of treatment are similar as for TB treatment in non-HIV patients. There are however, several important issues related to the treatment (Table 51.3). One needs to consider the HIV related problems, such as the compliance with the therapy, presence of drug resistance, the level of immunosuppression and presence of complicating or other coinfections. The outcomes of treatment in the presence of HIV infection are similar, if the basic principles are adequately taken care of.[58-60]

Antitubercular Therapy (Also see chapters 42 and 43)

The four primary drugs, rifampicin (R), isoniazid (H), pyrazinamide (Z) and ethambutol (E) constitute the main stay of treatment in drug-susceptible TB, administered as the standard two phase regimen: Initial intensive phase of two months of all the four drugs, followed by the maintenance phase of H and R for four months (2HRZE, 4HR). The treatment-strategy adopted in India in the RNTCP provides fairly comprehensive guidelines for the management. Under the strategy, the treatment to HIV positive patients referred from the Integrated Counseling and Testing Centres (ICTC), is provided at the tuberculosis control facilities, such as the DOTS centers as a coordinated activity.

Treatment of HIV-TB with DOTS has been shown to prolong the life,[61] prevent drug resistance and quickly render a TB patient noninfectious. It is the most effective method of promoting adherence to TB treatment, particularly in the presence of HIV coinfection.[62,63]

The issues related to intermittent versus daily regime and the optimum duration of therapy have remained somewhat debatable. Most of the studies of standard six month regimen (2 HRZE, 2 HR) have shown similar rates of treatment failure and relapse among HIV infected and non-HIV infected patients.[58,64,65] The current recommendation is to use standard six month regimen for all cases and to extend to nine months for patients with delayed clinical (continued symptoms) or microbiological response (sputum culture positivity) at two months.[66,67] The RNTCP guidelines provide similar recommendations.

Management of MDR-TB and XDR-TB in the HIV infected patients poses the biggest challenge. The choice of drugs and the duration of therapy for MDR-TB are variably recommended. Generally, the treatment duration is guided by AFB smear and culture reports. Most regimens contain four to six drugs, administered for at least 18 months after culture conversion, but extended to 24 months in patients with extensive pulmonary damage (Chapter 48).[68-70] The DOTS-Plus regimen for MDR-TB under the RNTCP comprises of six drugs (kanamycin, ofloxacin, ethionamide, Z, E and cycloserine) during the six to nine months of the intensive phase followed by four drugs (ofloxacin, ethionamide, cycloserine and E) for the 18 months of the continuation phase.[71]

A number of new drugs are there in various phases of development to reduce the number of drugs, as well as shorten the duration of therapy.[72,73] No drug as yet has proven to achieve the goals. Immunotherapy, including the new vaccines and vitamin D have also been used as adjunctive treatments.[74]

Antiretroviral Therapy (ART)

Concurrent treatment of both TB and HIV infections has significantly improved the outcome of patients.[74-76] HIV treatment with Highly Active Antiretroviral Therapy (HAART) comprises a combination of at least three Antiretroviral (ARV) drugs. There are four major groups of antiviral drugs, which are currently available that include:

- Protease inhibitors
- Reverse transcriptase inhibitors
- Viral integrase enzyme inhibitors
- Viral entry inhibitors (Table 51.4).

Antiretroviral treatment does not completely cure the disease, but effectively suppresses the viral replication. Antiretroviral therapy is costly and requires to continue life long. The ARV drugs also have a high-toxicity profile. There are several important issues in the administration of ART, especially when used along with antitubercular treatment (Table 51.3). The decision for HAART is best made in consultation with an HIV expert. The National AIDS Control Program (NACO) and WHO Guidelines are generally followed in resource limited countries.[77]

TABLE 51.4: Antiretroviral drugs

- I. Reverse Transcriptase Inhibitors
  - a. Nucleoside reverse transcriptase inhibitors
    1. Lamivudine
    2. Stavudine
    3. Zidovudine
    4. Didanosine
    5. Zalcitabine
    6. Emtricitabine
    7. Abacavir
    8. Tenofovir
  - b. Non-nucleoside reverse transcriptase inhibitors
    1. Nevirapine
    2. Efavirenz
    3. Delavirdine
    4. Etravirine
- II. Protease inhibitors
  1. Amprenavir
  2. Atazanavir
  3. Indinavir
  4. Nelfinavir
  5. Tipranavir
  6. Darunavir
  7. Saquinavir
  8. Lopinavir
  9. Ritonavir
- III. Integrase enzyme and viral entry inhibitors
  1. Raltegravir
  2. Enfuvirtide
  3. Maraviroc

The short-term risk of HIV disease progression in HIV related tuberculosis is related to the degree of immunosuppression (measured by CD4 cell count or CD4 cell percentage).[75,76] Patients with advanced immunosuppression (CD4 + T cell counts <100/μL) are likely to develop treatment failure, relapses and development of MDR-TB.

Use of Antiretroviral along with Antitubercular Therapy (ATT)

Combination of ART along with ATT has the potential of overlapping adverse effects of both therapies. Moreover, the presence of other opportunistic infections add further to the complication list. The HIV related complications (e.g. thrombocytopenia) cause additional problems. Drug-drug interaction is an important problem, especially seen with use of rifamycins, which increase the synthesis of a number of hepatic enzyme system. Rifampicin use results in a marked decrease in the concentrations of ARV agents, such as the protease inhibitors, which are metabolized by CYP3A. Rifabutin, with which the CYP3A expression is much less marked, is generally considered as an alternate drug. The dosages of these drugs, when used in combinations are therefore altered to maintain effective concentrations.[67,78-80] Thiacetazone should not be used in HIV-TB coinfection.

When to Start ART?

In view of the drug-drug interaction stated earlier, the ART was earlier withheld during the ATT administration. It is now believed that an early institution of ART helps in an early control of immunosuppression and improves mortality in patients with CD4 + T cell count of less than 200 cells/mm^3. In such patients, ART is started as soon as ATT is tolerated within the first two weeks to two months.[76] If the CD4 + T cell count is between 200 to 350 cells/mm^3, ART can start after the first two months of ATT. ART in patients with CD4+ counts of more than 350/mm^3 can be deferred until antitubercular therapy is completed.

In India, the integrated activities of the national programs, such as RNTCP and NACO, allow the treatment of HIV-TB coinfection. The ARV treatment is provided through the ART centers and ATT through the DOTS centers. The fewer number of ART centers however, is a limiting factor. The choice of regimens for ATT under RNTCP is made on the basis of standard categorization for different forms of tuberculosis irrespective of the HIV status. Regimens for MDR-TB are also being put in place at selected centers.

Immune Reconstitution Inflammatory Syndrome (IRIS)

Improvement in immunity following ARV therapy results in an increase in inflammatory response to mycobacteria in tuberculosis lesions. The worsening of clinical symptoms following institution of both ATT and ARV is termed as the IRIS.[81-83] This paradoxical reaction is often noticed particularly with lymph node and pleural tuberculosis.

The common features of IRIS comprise of fever and increase in lymphadenopathy, effusion and pulmonary infiltrates.[84,85] Occasionally, there is worsening of meningeal, central nervous system, hepatopulmonary, soft tissue or other forms of tuberculosis when it can even be life threatening.[85] The tuberculin skin reaction may frequently becomes positive.

Immune reconstitution inflammatory syndrome develops generally, in the presence of low baseline CD4+ cell count, a higher viral load and a shorter interval between the start of ATT and HAART. The presence of disseminated disease or a "better" response to treatment, i.e. a greater increase in the CD4+ cell count and a greater reduction in the viral load are other likely risk factors of IRIS.[86] Besides the "paradoxical" type of IRIS in which there is clinical worsening following ATT, an "unmasking" type of IRIS is also recognized in which the undiagnosed TB becomes apparent after the institution of HAART.[87] The pathogenesis of this unmasking is not clear, but it poses problems in the management.

Most cases of IRIS are self-limiting. Treatment with anti-inflammatory drugs, (usually nonsteroidal) is generally adequate. ATT and ART should not be stopped, but for very severe reactions.[88] Corticosteroids are rarely required for severe and persistent IRIS. On an average, IRIS lasts for a period of six to eight weeks, but for the presence of lymph node enlargement, which may persist for longer periods.

BCG Vaccination

BCG vaccination in an HIV positive child is a cause of concern in view of the reports of local complications and disseminated BCG disease. The risk is not substantiated by the results of prospective studies in HIV infected and non-HIV infected infants. As per current recommendations, routine BCG vaccination in infants in the high HIV prevalence areas is not withheld, but not given to known HIV infected individuals.[89]

Nontuberculous Mycobacterial Infections

PS Shankar, SK Jindal

INTRODUCTION

There are a large number of mycobacteria other than *Mycobacterium tuberculosis,* which are now being increasingly recognized as a cause of human disease. Commonly referred to as Nontuberculous Mycobacteria (NTM), they are also known as atypical mycobacteria, anonymous mycobacteria, or Mycobacteria Other Than Tubercle bacilli (MOTT). They are weak pathogens and they are distinct from *Mycobacterium tuberculosis* in their characteristics. NTM are ubiquitously distributed in the environment and hence also known as environmental mycobacteria. Often these bacteria inhabit the respiratory passages in the form of commensal organisms. Pulmonary infection from NTM though rare, can cause disease similar to tuberculosis. They more commonly infect the skin, soft tissue, lymph nodes, implant devices, wounds, bones and joints. Occasionally, the infection is disseminated systemically in patients who are immunosuppressed or who have Acquired Immunodeficiency Syndrome (AIDS).

Classification

Runyon's classified atypical mycobacteria into four groups based primarily on colony morphology, pigmentation and growth characteristics.[1]

Group I consists of photochromogens. *Mycobacterium kansasii* is an important pulmonary pathogen belonging to this group. It grows slowly over two to four weeks and becomes yellow on exposure to light. *Mycobacterium scrofulaceum* belongs to Group II and is a scotochromogen. It grows slowly over two to four weeks and produces yellow colonies even in dark. It turns orange on exposure to light. *M. scrofulaceum* affects cervical lymph nodes. It occurs exclusively in children.

Nonchromogens belong to Group III. They grow slowly and produce white colonies that do not change color on exposure to light. *Mycobacterium avium* and *Mycobacterium intracellulare* (Mycobacterium avium complex or *Mycobacterium avium* and *M intracellulare,* MAI) belong to this group, and are responsible for pulmonary lesions, or cervical lymphadenopathy, and occasionally may also cause a virulent disseminated disease. The organisms, which belong to Group IV grow within three to five days on culture, and are hence referred to as "rapid growers." They do not change color on exposure to light. *Mycobacterium fortuitum, Mycobacterium chelonei* and *Mycobacterium smegmatus* are examples of this group. They often produce subcutaneous abscesses.

More recently, the mycobacterial species are classified on the basis of genetic differences, such as the sequence differences in the 16S ribosomal RNA. The NTM species are divided into rapid and slow growers. They also vary in their nutritional requirements and grow on either the simple media or on the media supplemented with nutrients.

Human Disease

Though the nontuberculous mycobacteria are widely distributed in the environment, the clinical infection is rare.[2] They may be falsely recovered from clinical specimens due to laboratory contamination or contamination of medical instruments. More than

TABLE 52.1: Some of the important nontuberculous mycobacterial species linked with disease in humans

Mycobacterium avium
M. intracellulare
M. kansasii

M. habana
M. interjectum
M. genavense
M. xenopi
M. marinum
M. malmoense
M. fortuitum
M. ulcerans
M. chelonei
M. smegmatis
M. xenopi
M. hemophilum

90 species of NTM have been recognized. Of them nearly one-third have been linked with disease in humans (Table 52.1).[3,4]

Chronic pulmonary infection due to *M. avium* complex and *M. kansasii* generally occurs in elderly persons. Cervical lymphadenopathy occurs in children due to *M. scrofulaceum*, while skin and soft tissue infections may develop from *M. fortuitum*, *M. chelonei, M. xenopi* and *M. ulcerans*. Exposure of humans to NTM may occur while bathing, swimming and drinking, and the organism can also gain entry through cuts and abrasions. However, the risk of infection is generally less. Disseminated lesions are found in immunocompromised patients due to infection from *M. avium* complex. Sometimes, *M. chelonei* may cause very indolent pulmonary infection.

Epidemiology

Nontuberculous mycobacteria are commonly isolated from soil, water and house dust except *M. kansasii* whose natural reservoir remains undetermined.[5] *Mycobacterium Avium Intracellular Complex* (MAIC) is commonly recovered from residential bath rooms and showers.[6,7] Colonization of human body especially of upper airways, skin and gastrointestinal tract by NTM is common without any evidence of disease. The pulmonary infection appears to result from the inhalation of infectious droplets that have been aerosolized from the environmental sources. Ingestion of organism especially *M. avium* complex by patients with AIDS infects the gastrointestinal tract and gets disseminated. Direct inoculation may result in the infection of skin, soft tissues and joints. Human-to-human transmission is very unusual.[5] Familial clustering, however, is reported that suggests the role of genetic factors contributing towards host susceptibility.[8]

The infection from NTM has been reported from the different parts of the world especially United States, Europe and Japan. In the United States, a rising prevalence of sensitization of one in six persons was reported in 1999-2000, up from one in nine persons in 1971-1972.[9] The infection from NTM has been reported infrequently in India. However, the frequent occurrence of low-grade tuberculin reaction suggests a varying risk of human disease. NTM may be responsible for a significant proportion of mycobacterial infections in HIV seropositive patients. Due to the higher endemicity of tuberculosis in India, the presence of NTM should be ruled out especially in immunocompromised HIV seropositive patients.[10]

In India from Agra, 119 isolates of environmental mycobacteria were grown from 291 (116 soil and 175 water) samples, gene amplification restriction analysis confirmed the identity of 85.7% isolates and the remaining 17 isolates by 16S rRNA sequencing.[11] The isolates included pathogenic species such as *M. fortuitum, M. chelonei, M. avium* and *M. kansasii.*

In a study at Puducherry, South India, among 22 isolates of mycobacteria isolated from 635 samples of suspected tuberculosis, 17 were of *M. tuberculosis*, 3 of *M. kansasii* and one each of *M. fortuitum* and *M. gordonae.*[12] The study has highlighted the importance of NTM as potential pathogens from both pulmonary and extrapulmonary sites.

In another study from Guwahati, north-eastern India, in 25 pus/discharge specimens from non-healing postoperative wound infections that did not respond to antibiotics, 20 revealed growth of NTM sp.[13] All of them were identified as *M. fortuitum-chelonei* complex. The sputum specimens from 6,829 patients diagnosed as "relapsed cases" of pulmonary tuberculosis and chronic nonspecific respiratory disease were cultured for the growth of Acid-Fast Bacilli (AFB) at Manipal, coastal Karnataka, India. In this sample, growth in 13.7% cases was due to atypical mycobacteria.[14]

Clinical Features

Infection in a healthy person from NTM (commonly *M. kansasii* and *M. avium* complex) presents a picture of chronic pulmonary disease resembling tuberculosis. The lung infiltrates are more diffuse and nodular in appearance. Cavitary disease is common. Mediastinal lymph node involvement and pleural effusion are uncommon. The lymph nodes, skin, soft tissues, bones and joints are other important sites of NTM infection.[4]

NTM infection maxy present in one of three different forms: A tuberculosis-like pattern; nodular bronchiectasis and hypersensitivity pneumonitis.[15] The classical TB-like presentation commonly occurs in older male smokers frequently with underlying chronic obstructive pulmonary disease. It is more indolent than typical tuberculosis and presents with cough and expectoration. Though there can be fever, night sweats, weight loss, and hemoptysis occasionally, these constitutional symptoms are less severe. The progress of the disease is slow. These patients may have preexistent pulmonary diseases such as Chronic Obstructive Pulmonary Disease (COPD), bronchiectasis, silicosis and even prior pulmonary tuberculosis. In such situations, the features of infection due to NTM may pose difficulty to distinguish from those of the underlying disease. The disease is commoner in persons with diabetes and those having a history of smoking.

A "non-classical" form of illness has also been described. It is noted in elderly nonsmoker women. Though the condition has an insidious onset with chronic cough, it is not associated with any pre-existing lung disease seen in "classical" form. The constitutional symptoms are rare.[6] Hypersensitivity pneumonitis may present a typical episodic picture on exposure to bacteria such as to *Mycobacterium avium* complex. MAC infection can present with any of the three different forms: Classical, non-classical or disseminated.[15]

The disseminated infection may occur in patients with immunosuppression due to hematological malignancy or use of immunosuppressive agents.[16] Its incidence has shown an increase in patients with advanced stages of AIDS especially when the infection is due to *M. avium* complex.[4,12] The condition presents with persistent fever, weight loss, anorexia and weakness. The pulmonary symptoms are infrequent and exhibit cough or dyspnea. There can be vomiting, diarrhea and abdominal pain. There is generalized lymphadenopathy, hepatomegaly, splenomegaly and nodular skin lesions. The condition is noted in children and young adults.

Diagnosis

Diagnosis of NTM pulmonary disease is made on the basis of the presence of a variety of clinical, radiological and microbiological criteria, several of which may only suggest the diagnosis. The exact disease etiology then needs to be confirmed (Table 52.2).

TABLE 52.2: Guidelines for making the diagnosis of NTM-pulmonary disease

i. Clinical features of an indolent, respiratory disease – cough, expectoration, fever and other constitutional symptoms.
ii. Positive smear for AFB and/or heavy growth of NTM on culture in respiratory specimens.
iii. Histopathological features of mycobacterial/granulomatous disease or culture of NTM from biopsy specimens.
iv. Radiological features of nodular infiltrates with or without cavitation and/or bronchiectatic lesions.
v. Underlying host conditions: Immunosuppression, AIDS, alcoholism, COPD, cystic fibrosis, diabetes, malignancies, etc.
vi. Absence of other causes of pulmonary lesions, such as tuberculosis, aspergillosis, etc.
vii. Persistence of AFB after antituberculosis treatment for two weeks or more.

Radiology

The radiographic appearance in the "classic" form of disease resembles chronic indolent tuberculosis. The most common radiological pattern is the presence of fibronodular infiltrates involving the upper lobes especially apical and posterior segments.[13,17] Unlike tuberculosis, the cavities are thin-walled with little surrounding infiltrate. The "non-classical" form of disease is characterized by multiple bilateral opacities, similar to those in bronchiectasis. The infiltrates are seen predominantly in middle lobe and lingula and are not associated with apical shadow resembling post-primary tuberculosis.[10]

The pleural involvement, especially effusion, is rare. CT of the chest defines the radiologic features precisely. Small nodular opacities are seen in the regions of maximal disease and also in areas away from the predominant site of the disease. Changes related to bronchiectasis are present adjacent to the apical cavities in the "classical" form. In non-classical form of disease, bronchiectasis is bilateral and widespread.

Disseminated form of disease may not show any radiological abnormality or exhibit bilateral infiltrates. It may be associated with hilar or mediastinal adenoapathy and/or pleural effusion.[14] The radiological abnormalities are more likely to be produced by coexistent conditions in AIDS patients.

Bacteriology

Since NTM may colonize the respiratory tract of patients with preexisting lung disease, their isolation from sputum, bronchial washings or lung biopsy may not establish the infection. In a study from Korea, only about a fourth of 794 patients from whom NTM was isolated from respiratory specimens were found to have clinically significant NTM lung infections.[18] Repeated sputum cultures demonstrating heavy growth of NTM are necessary to pinpoint NTM as the etiologic agent, in a patient with compatible clinical picture and radiograph. However, there is no need for repeated isolation of *M. kansasii* as it rarely occurs in the form of a saprophyte. In disseminated form, blood culture demonstrates causative agent. The NTM are traditionally classified as rapid and slow growers on the basis of their growth. Other bacteriological investigations, which are employed for identification include the biochemical tests such as serotyping and protein electrophoresis. The newer molecular methods, such as the gene probes and gene amplification (polymerase chain reaction) are now available for the detection of NTM, such as *M. avium, M. intracellulare* and some rapid growers. More advanced techniques, such as DNA fingerprinting are sometimes used for the characterization of NTM.

Histopathological dissection of granulomas with or without AFB staining in biopsy specimens from lymph nodes, liver, bone marrow or lungs may also help in the diagnosis. Immunodiagnostic techniques, such as the "Regions of Difference (RD) antigens," encoded proteins have been used for the diagnosis of both latent and active tuberculosis. Some of these RD antigens are located in the genome of *M. tuberculosis, M. africanum and M. bovis,* but absent in many of NTM and Bacillus-Calmetter-Guérin (BCG) substrains.[19] However, their role in the diagnosis or exclusion of NTM infection yet remains to be esta-blished.[19]

Treatment

The disease produced by NTM makes a slow progress, though it may remain stable for long periods. The disseminated form of disease has a rapid fatal course. NTM except *M. kansasii* may exhibit a high degree of in vitro resistance to many of the standard antituberculosis drugs.

Treatment in NTM infection is indicated only if the organism is causing the disease and is not simply a colonizer. Multiple antimicrobials are required for prolonged periods.[20,21] The infection from *M. kansasii* is treated with a combination of isoniazid, rifampicin and ethambutol (15 mg/kg) for 18 months.[22] Pyrazinamide largely remains ineffective.

The treatment of infection due to *M. avium* complex is difficult. Multidrug therapy is indicated in patients exhibiting a progressive course or those who are severely ill. Treatment consists of a macrolide, rifampicin and ethambutol given three times weekly for noncavitary disease and daily with or without an aminoglycoside for cavitary disease.[23] The choice of drugs depends upon the isolated NTM and the severity of manifestations (Table 52.3). The success rate is low particularly in the AIDS patient as the organisms are usually resistant to most of the commonly available antituberculosis drugs, including isoniazid.

TABLE 52.3: Suggested drugs for the treatment of infections with common NTM-isolates

NTM	*Suggested drugs*
1. *M. avium intracellulare*	H,R,E Aminoglycosides (Streptomycin, Amikacin) Quinolones (Ciprofloxacin/Ofloxacin) Clofazimine Macrolides (Clarithromycin/Azithromycin)
2. *M. fortuitum/ M. chelonei*	Amikacin/Streptomycin Macrolides Doxycycline Cefoxitin Imipenem
3. *M. kansaii*	H,R,E
4. *M. ulcerans*	Surgery (with or without drugs as for *M. fortuitum*)
5. *M. scrofulaceum*	Surgical excision H,E, cycloserine Macrolide

(H = Isoniazid, R = Rifampicin, E = Ethambutol)

Disseminated lesions due to *M. avium* complex in AIDS patients may be treated with rifampicin, ethambutol, clofazimine and ciprofloxacin. Those exhibiting stable disease are observed and underlying pulmonary disease is treated with bronchodilators, antibiotics (if sputum is purulent) and smoking cessation. Mycobacterial disease may get eradicated without specific therapy. When specific treatment is initiated, it consists of isoniazid, rifampicin and ethambutol (25 mg/kg for the first 2 months followed by 15 mg/kg) with an initial supplementation of streptomycin for three to six months.[22,23] Treatment has to be given for 18 to 24 months. For the patients exhibiting an extensive disease and those who fail to show sputum conversion on the four drug regimen, additional drugs, such as cycloserine and ethionamide are to be added to the therapeutic regimen. Surgical resection of the lesion may be undertaken in those having a localized disease. Some newer agents that may be active against NTM are rifabutin, clarithromycin, azithromycin and ofloxacin.[24-27] *M. chelonei* is generally resistant to the antituberculosis drugs and other conventional antibiotics. It shows susceptibility only to amikacin, cefoxitin and imipenem.

Nonpulmonary Manifestations

Nonpulmonary features of NTM infection are more common than that of tuberculosis. Infection of the extrapulmonary sites may occur through skin-contact, penetrating injuries, ingestion of contaminated water or aerosol inhalation. Hematogenous spread may be responsible for disseminated disease.

Lymphadenitis

Several NTM species have been identified to cause cervical lymphadenitis in healthy individuals, especially in children. MAC group is the most common species in both the immunocompetent and the immunosuppressed patients.[28-30] Presence of cervical lymphadenopathy in an adult with HIV infection or with organ transplantation on immunosuppressive therapy should always arouse the strong suspicion of MAC infection. The other causative organisms may include *M. scrofulaceum* and *M. malmoense*. Constitutional symptoms are generally absent. Poor response to standard antituberculosis therapy or repeated appearance of lymph nodes inspite of therapy arouses the suspicion of NTM-lymphadenopathy. The lymph nodes may also undergo central caseation, or lead to development of sinuses or abscess formation. Surgery should be considered for treatment in addition to the antimicrobial therapy.

Skin and Subcutaneous Abscesses

Skin gets commonly infected following penetrating injury, inoculation or surgery with contaminated instruments. Clusters of cases of incisional and subcutaneous abscesses are reported following laparoscopic surgery especially when performed in camps. A series of 145 laparoscopy post site infections were found in 35 patients following laparoscopy at a single hospital, where the water was used for washing chemically disinfected instruments.[30] The organism *M. chelonei* in this report had survived and grown within the biofilm at the bottom of the disinfectant trays.

Inoculation of superficial skin and subcutaneous infections as above are commonly caused by the rapidly growing mycobacteria, such as *M. fortuitum, M. chelonei, M. ulcerans, M. marinum* and *M. abscessus. M. fortuitum* and *M. chelonei* are sometimes responsible for deeper lesions, as well as disseminated infections, for example following the cardiac surgery. The rapid growers may occasionally cause superficial, intestinal ulceration, although the mere isolation from feces or colonoscopic specimens does not conclude a causal relationship with the gastrointestinal disease.

Treatment of infections with rapid growers consists of combined antibiotic therapy from amongst aminoglycosides, macrolides, doxycycline and fluoroquinolones. A prolonged course of 12–24 months treatment is generally required.

Disseminated NTM Infection

Disseminated disease with NTM generally occurs in patients with HIV infection. Several other groups of diseases and clinical conditions are now described where NTM are recognized as responsible pathogens. Renal transplant recipients and patients with underlying treatment for rheumatic disease, cystic fibrosis, lymphomas, leukemia and disseminated malignancies are particularly liable.[31-33] An increasing trend in non-HIV infected patients was reported from Thailand. Only 12% of 129 patients had an underlying disease.[34] The patient in this series reported with lymph node, skin, soft tissue and lung involvement, sometimes with coinfection from other opportunistic organisms.

Disseminated disease may present rarely with localized lesions in the central nervous system, kidney, liver, joints, bones and multiple lymph nodes. Constitutional symptoms are common with multiple organ involvements. Involvement of multiple sites may sometimes mimic metastases on PET/CT scans.[35]

Nontuberculous Mycobacteria Infections in Children

Nontuberculous mycobacteria infection is frequently recognized in children. In a nationwide active surveillance network amongst Australian children, the NTM was isolated in 68 cases with MAC being the most frequent organism.[36] In children, the NTM infection is typically associated with lymphadenopathy, while pulmonary involvement is rare in otherwise healthy children.[36]

Isolated pulmonary NTM disease is recognized more commonly in patients with cystic fibrosis.[33,37,38] Occasionally, pulmonary NTM-infection in otherwise healthy children, presenting with refractory stridor or wheezing with endobronchial lesions or hilar lymphadenopathy without any recognized underlying immune deficiency or CFTR mutations has also been described.[37]

Miscellaneous Clinical Manifestations

Besides the pulmonary manifestations, lymphadenitis, skin and soft tissue infections, several other organs may also show isolated or disseminated NTM involvement. MAC disease, which commonly occurs in patients with HIV infection, may involve the eyes (corneal ulcers), heart (endocarditis), central nervous system (meningitis) and bones (osteomyelitis). Similar involvement may rarely occur with *M. fortuitum*, a chelonae group of mycobacteria. Meningitis and hepatitis are known to occur with *M. scrofulaceum* and *M. gordonae*. *M. smegmatis*, the first mycobacteria identified after *M. tuberculosis* is found to be associated with pneumonia, sternotomy wound infections and soft tissue infections.[39] *M. bovis* was commonly considered responsible for lymphadenitis and gastrointestinal manifestations due to the ingestion of milk from infected cows before the pasteurization era. A report of 73 cases, seen during a 12-year period was described from San Diego.[40] More recently, the cases are reported to occur in patients with HIV infection and those working in the cattle farms or slaughter houses.

In summary, an increased trend of NTM infections is recognized, especially in patients with HIV infection or with the other causes of immunosuppression. Pulmonary manifestations and lymphadenitis are most common, while disseminated forms, skin and soft tissue involvement may also occur. Diagnosis is established on the basis of clinical features, radiological and microbiological investigations. Treatment is somewhat difficult requiring multiple drugs for prolonged periods.

Community-acquired Pneumonia

Charles Feldman, Ronald Anderson

INTRODUCTION

Community-Acquired Pneumonia (CAP) is described as a lung infection, acquired in the community, most commonly bacterial in nature, associated with the inflammation of the lung parenchyma, distal to the terminal bronchiole, with clinical and radiological evidence of consolidation of part or parts of one or both lungs. It is an extremely common infection that causes considerable morbidity and mortality, even in the modern world, especially among the very young, the elderly and patients with underlying comorbid disease.[1] The overall mortality of CAP varies from less than 1% in outpatients to approximately 14% in cases admitted to hospital and to 50% or more in patients requiring intensive care unit admission.[1-3] CAP puts an enormous burden on medical and economic resources, particularly if patients are hospitalized, since this is associated not only with direct hospital costs, but also with intensified laboratory investigation and broader empirical anti-microbial chemotherapy.[1,4] Studies from the United States,[1] Europe[4] and the United Kingdom[5,6] attest to the considerable burden of disease that is associated with this infection in the developed world. Furthermore, most countries in Africa and Asia have two to ten times more pneumonia in children than in the United States. In the Asian region, the two most populous countries, namely China and India, contribute significantly to these numbers.[7] In developing countries like India, infectious diseases, including pneumonia are a leading cause of mortality, particularly among the lower social classes.[8] One review of the burden of pneumonia indicated that in children, pneumonia was estimated to be the cause of approximately 2 million deaths per year (20% of all childhood deaths), with 70% of these deaths occurring in Africa and Asia.[7]

EPIDEMIOLOGY

A number of studies have investigated in detail the global and regional burden of diseases in the world.[9-11] As early as 1990, the Global Burden of Disease Study using Disability-Adjusted Life-Years (DALYs) compared disease and death in different regions of the world.[9] Lower respiratory infections were the most common specific cause of global DALYs and the highest disease burdens were in sub-Saharan Africa (21.4%) and India (20.9%). In 2001, slightly more than 56 million people died.[10] Five of the ten leading causes of death in low- and middle-income countries were infectious diseases, including lower respiratory tract infections, which were the most common infectious cause, being even more common than Human Immunodeficiency Virus (HIV)/ Acquired Immunodeficiency Syndrome (AIDS), diarrheal diseases, tuberculosis and malaria.

Similarly, in 2002, it was reported that slightly over 57 million people died in the world with lower respiratory tract infections, being the third leading cause of death (3.94 million deaths–6.9% of total deaths).[11] Lower respiratory tract infections were the second leading cause of burden of disease in low- and middle-income countries as measured by DALYs [92.2 DALYs (millions) – 6.7% of total DALYs.][11] In sub-Saharan Africa, lower respiratory tract infections were the second leading cause of disease burden (second only to HIV/AIDS) [37.2 DALYs (millions)–10.0% of all DALYs.][11]

One factor that has contributed significantly to the impact of CAP, particularly in patients in sub-Saharan Africa, has been the associated epidemic of human immunodeficiency virus (HIV) infection.[12] Worldwide, more than 40% of new HIV infections have occurred in adults aged 15–24 years, with 95% of these infections and associated deaths having occurred in developing countries. Sub-Saharan Africa is home to almost 64% of persons living with HIV and this burden is seen particularly among women.[12] However, a number of studies attest to the fact that the HIV epidemic is growing very rapidly in Asia, particularly in countries such as India and especially among the youth, such that an epidemic may be faced on the same scale as that in sub-Saharan Africa.[13-16] Pulmonary infections, including tuberculosis, opportunistic infections, but also CAP occur much more commonly in HIV-infected persons than in non-immunocompromised individuals and CAP is second among the pulmonary complications.[17,18]

MICROBIAL ETIOLOGY OF COMMUNITY-ACQUIRED PNEUMONIA

While CAP may be caused by a wide range of pathogens, in reality the majority of cases are caused by a relatively small number of predominantly bacterial pathogens, even among HIV-infected patients.[1] By far, the most common pathogen is *Streptococcus pneumoniae,* which accounts for some 20 to 80% of cases and remains the commonest pathogen even among cases requiring intensive care unit admission.[1,3] In HIV-infected patients, as in non-immunocompromised cases, *S. pneumoniae* remains the most common pathogen in CAP.[17] Interestingly, on the basis of initial studies, it was commonly believed that *Pneumocystis carinii* (now called *Pneumocystis jirovecii*) was an uncommon cause of infection and/or death in patients in the developing world with HIV infection; however this was probably as a consequence of the lack of recognition, and subsequent studies indicated its common occurrence in countries such as South Africa and India.[19-21]

Table 53.1 shows the prevalence of the common etiological agents of CAP.[3] A number of studies have been conducted in India with the aim of identifying the common bacterial pathogens associated with CAP. One study in Shimla (in India) using sputum, blood and pleural fluid culture, and serology for *Mycoplasma pneumoniae* identified 70 patients with CAP of whom 53 (75.5%) had an identifiable cause and 12 patients were noted to have mixed infections.[22] No cause was identified in 17 patients despite extensive investigation, including the bronchoscopic aspiration of respiratory tract secretions. The most frequent pathogens were *S. pneumoniae* (19; 35.8%), *Klebsiella pneumoniae* (12; 22%), *Staphylococcus aureus* (9; 17%), *M. pneumoniae* (8; 15%), *Escherichia coli* (6; 11%), beta-hemolytic streptococci (4; 7.5%) and other gram-negative bacilli (5; 9%). Another study from Chennai, which noted that the prevalence of infection with *M. pneumoniae* was comparatively higher in HIV-infected persons when compared with HIV-noninfected adults, also documented *S. pneumoniae* as the most common cause of lower respiratory tract disease.[23] A study from New Delhi documented the serological evidence of *Legionella pneumophila* infection in 9 of 60 patients (15%) admitted to the All India Institute of Medical Sciences with CAP and the authors suggested that infection with *Legionella spp*., may be a more frequent cause of CAP than previously recognized and recommended that empirical antibiotic therapy should

TABLE 53.1: Pathogens associated with community-acquired pneumonia**

	Relative frequency (%)
• *Streptococcus pneumoniae*	35%–80%
• *Haemophilus influenzae*	5%–6%
• Atypical pathogens	
— *Legionella spp.**	2%–15%
— *Mycoplasma pneumoniae*	2%–14%
— *Chlamydia spp.* †	4%–15%
• *Staphylococcus aureus*‡	3%–14%
• Enteric Gram-negative bacilli§	6%–12%
• *Pseudomonas aeruginosa*¶	4%–9%
• *Coxiella burnetii*	2%–4%
• *Moraxella catarrhalis*	<1%
• Influenza A virus	10%–15%
• Other viruses»	5%–10%
• *Mycobacterium tuberculosis*¥	<1%–5%
• Unknown	15%–40%

*Vary in importance between countries; more than 95% are *L. pneumophila* serogroup 1; outbreaks are common.

†More than 99% due to *Chlamydophila pneumoniae* in adults.

‡Increasing in areas with high prevalence of community-acquired methicillin-resistant *S. aureus*.

§Main species associated with CAP are *Escherichia coli* and *Klebsiella pneumoniae.*

¶Risk factors include chronic steroid therapy, structural lung disease, previous hospitalization.

»Including respiratory syncytial virus, adenovirus, parainfluenza virus, metapneumovirus, varicella-zoster virus, measles and hanta virus.

¥Relative frequency varies considerably in different parts of the world.

include a combination of agents that cover both "atypical" and conventional bacterial pathogens.[24]

A number of studies have been undertaken in India in order to document the pneumococcal serotypes causing invasive disease and/or respiratory tract infections.[25-27] These studies have frequently documented serotypes 1, 6, 19, 7 and 5 to be the most common, with serotype 23 emerging in the later years. Among these isolates that were serotyped, resistance to co-trimoxazole, tetracycline and chloramphenicol was found to be common, whereas resistance to penicillin was infrequent and if present, was of intermediate resistance.[26-28] The prevalence of macrolide resistance in India has also been documented to be very low, as opposed to a number of other countries in Asia.[29] However, a number of investigators throughout India and Asia are continuing to report the increase and spread of penicillin resistant and even multidrug resistant, invasive and colonizing, *S. pneumoniae* isolates.[30-35] Clearly, these investigators recommend that when choices of empirical antimicrobial therapy are made, they need to take into account local susceptibility patterns of the common infecting microorganisms.

RISK FACTORS FOR COMMUNITY-ACQUIRED PNEUMONIA

Risk factors for CAP are many and varied and include among many other factors, extremes of age (very young and the elderly), underlying comorbid conditions [in particular cardiovascular disease, chronic obstructive pulmonary disease (COPD) and HIV infection], lifestyle factors [including excessive alcohol consumption, cigarette smoking, and variations in body mass index (malnutrition or obesity)], various medical treatments, and socioeconomic factors (Table 53.2).[36-43] The exact mechanisms by which these conditions actually predispose to pneumonia is unclear, but in general terms they may predispose to an increase in bacterial colonization of the airway, and/or allow direct access of the bacteria to the lower respiratory tract, and/or be associated with impairment of normal host defences and/or clearing mechanisms. In the case of the elderly, it appears that it may not be simple chronological age that is the important risk factor, but rather the underlying comorbid conditions that commonly exist in the aged. HIV infection itself is a risk factor for CAP, even in the era of Highly Active Antiretroviral Therapy (HAART), but the exact mechanisms are uncertain and are the subject of ongoing investigations. Many of the usual risk factors for pneumonia that exist in non-immunocompromised patients also act as risk factors in HIV-infected persons.[44,45]

TABLE 53.2: Risk factors for community-acquired pneumonia*

- Extremes of age (very young and the elderly)
- Low socioeconomic status
- Lifestyle factors (cigarette smoking, excessive alcohol use, malnutrition or conversely high BMI)
- Underlying comorbid conditions (chronic cardiovascular, respiratory and renal disorders)
- HIV infection
- Other immunodeficiencies
- Medications

Many of the studies documented above, as well as several others, have clearly indicated the substantial role that cigarette smoking plays as a major risk factor for CAP, in both HIV-infected and uninfected individuals.[37,46-52] The exact mechanisms by which cigarette smoking predisposes to pneumonia are uncertain, but are almost certainly multifactorial and cigarette smoking has multiple effects on host defences. Nasopharyngeal colonization by microorganisms, such as the *Pneumococcus* is an essential first step in the pathogenesis of pneumococcal infections (see below). Cigarette smoking and exposure to tobacco smoke has clearly been shown to increase pneumococcal carriage rates in both adults and children[53] and therefore, represents a major risk factor for pneumonia. The importance of cigarette smoking as a risk factor for nasopharyngeal colonization has been shown in south Indian infants, who experience high rates of pneumococcal carriage in the first six months of age, at least partly explaining their increased risk of pneumonia.[54] In that study, the odds of pneumococcal carriage were significantly increased in infants living in households in which 20 or more cigarettes were smoked each day. Interestingly those same investigators documented that vitamin A supplementation at birth, delayed the onset of pneumococcal colonization.[55]

Cigarette smoking may also enhance the risk of CAP because of its association with COPD. The population prevalence of COPD is very high in India, the risk being related to the smoking of *bidis* and cigarettes, as well as environmental tobacco smoke exposure in non-smokers.[56] In a study in Shimla (in India), in addition to extremes of age, smoking and underlying COPD were significantly associated with the development of CAP.[22]

PATHOGENESIS OF CAP WITH PARTICULAR REFERENCE TO THE PNEUMOCOCCUS

Virulence Factors and Pathogenesis

The section will focus on *S. pneumoniae*, the most common bacterial cause of CAP. Pneumococcal colonization of the airways is mostly asymptomatic, but is nevertheless the first step in the pathogenesis of invasive disease. This may be precipitated by infection with respiratory viruses, resulting in the increased expression of receptors for bacterial adhesins on airway epithelium.[57]

Biofilm Formation

Prior to reviewing virulence factors, a brief consideration of the role of biofilm in microbial colonization/persistence is important, as this is a strategy utilized by the *Pneumococcus* to evade host defences.[58] Biofilm also restricts the penetration of antibiotics, favoring antibiotic resistance. Importantly, the *Pneumococcus*, by the mechanisms described below, adheres to and invades airway epithelium. Biofilm-encased bacterial aggregates attached to the epithelial surface, or sequestered intracellularly, therefore provide an effective mechanism for bacterial persistence.[58] Concealed in biofilm, in which it communicates by quorum sensing mechanisms, the *Pneumococcus* can reemerge at times, when host defences are transiently or irreversibly compromised, as may occur during infection with influenza virus/respiratory syncitial virus or HIV-1, respectively.

Virulence Factors

The polysaccharide capsule is generally recognized as being the major virulence factor of the *Pneumococcus*, promoting resistance to both entrapment by mucopolysaccharides present in mucus and opsonophagocytosis. Other non-protein virulence factors include hydrogen peroxide and phosphorylcholine. Hydrogen peroxide promotes structural damage to respiratory epithelium, interfering with the protective activities of the mucociliary escalator,[59] favoring attachment of the *Pneumococcus* to epithelial cells via the interaction of phosphorylcholine with the platelet-activating Factor (PAF) receptor.[60,61]

The *Pneumococcus* also possesses an array of protein virulence factors, which contribute to evasion and/or suppression of host defences. Some of these are recognized as potential vaccine candidates and include the choline binding proteins (Cbps), neuraminidase, hyaluronidase, zinc metalloproteinase, divalent metal-binding proteins, the pneumococcal lipoprotein surface adhesin A (PsaA) and the cholesterol-binding, pore forming toxin, pneumolysin, generally recognized to be the most potent of the pneumococcal protein virulence factors. During colonization of the nasopharynx, virulence factors that neutralize both innate and adaptive host defences enable bacterial adhesins to promote attachment of the *Pneumococcus* to airway epithelium. In addition to the polysaccharide capsule, the pneumococcus utilizes numerous strategies to subvert innate and adaptive host defences. These include: i) interference with the protective actions of the mucociliary escalator, primarily by pneumolysin, acting in concert with hydrogen peroxide and hyaluronidase;[59,62] ii) interference by PspA and PspC (also known as CbpA) with activation of the alternative complement pathway; iii) pneumolysin-mediated depletion of complement via activation of the classical pathway; and iv) cleavage of secretory IgA by the zinc metalloproteinase, favoring adhesion of the *Pneumococcus*.[60,61,63]

Notwithstanding the pro-adhesive interactions between pneumococcal phosphorylcholine and the PAF receptor on airway epithelium, PspA and PspC also promote attachment via binding to the epithelial polymeric Ig receptor that normally transports secretory IgA, while E-cadherin, the cell-cell junction protein of respiratory epithelium is a receptor for PsaA.[60,64] In addition, some serotypes possess pilus-like structures that promote epithelial adhesion via interaction with uncharacterized receptors. A novel pneumococcal protein adhesin has been described recently. This is the 120 kDa plasminogen- and fibronectin-binding protein B (PfbB), which significantly increases the ability of the pneumococcus to adhere to epithelial cells.[65] Unmasking of these various pneumococcal adhesins necessitates a reduction in capsule size, with the accompanying risk of increased vulnerability to phagocytosis. This is apparently minimized by production of biofilm, a process in which bacterial neuraminidase[66] and possibly H_2O_2 participate. These aforementioned virulence mechanisms facilitate the translocation of the pneumococcus to the lower airways, while transcytosis of the pathogen across the epithelial barrier via the polymeric Ig receptor enables access to the bloodstream and invasion of the central nervous system.

Antipneumococcal Host Defences

Although nasopharyngeal colonization by the pneumococcus is the first stage in invasive disease, it may also protect against severe infection by activating host defences.[67] Innate and adaptive immune responses triggered by the aforementioned virulence factors, as well as cell wall components such as lipoteichoic acid (LTA) and proteoglycans, if efficiently mobilized, can control and eradicate pneumococcal colonization.

Innate Host Defences

Interactions of LTA and pneumolysin with toll-like receptors (TLRs) -2 and -4, respectively, result in the mobilization of circulating neutrophils to the airways. These TLRs are the prototype pattern recognition molecules, which function as the sentinels of the innate immune system. Interaction of LTA and pneumolysin with TLRs on airway epithelium and other cells of the innate immune system in the airways, triggers a signalling cascade, which leads to the production of the cytokines, interleukin (IL)-1β, IL-6 and tumor necrosis factor (TNF), as well as the chemokine IL-8, all of which cooperate to promote transendothelial migration and the chemotaxis of neutrophils. In addition, Nucleotide Oligomerization (NOD)-like receptors also contribute to innate anti-pneumococcal host defences. These are a specialized group of intracellular pattern recognition molecules, which like TLRs recognize highly conserved structures on bacterial pathogens. In the case of the pneumococcus, bacterial proteoglycans are recognized by epithelial NOD proteins, specifically NOD-2, resulting in the production of pro-inflammatory cytokines/chemokines and influx of neutrophils. This TLR/NOD-2-mediated inflammatory response contributes to the early control of colonization and also favors adaptive mucosal immunity by promoting the degradation of bacteria required for efficient delivery of pneumococcal antigens to nasal-associated lymphoid tissue.[68-71]

Adaptive Host Defences

IgG and secretory IgA antibodies directed against the polysaccharide capsule of the pneumococcus are generally considered to be the primary determinants of immune-mediated type specific protection. Antibodies to pneumococcal proteins, particularly CbpA, PsaA and pneumolysin also confer protection, which although less efficient, are not serotype restricted.[72] Based on experimental animal and clinicoepidemiological studies, it is now evident that antibody-independent, $CD4^+$ T cell-mediated adaptive immune responses to pneumococcal protein antigens also contribute to the natural development of immunity to pneumococcal infection.[60,73,74] T lymphocytes of the TH1 and TH17 subsets appear to be critically involved in these cell-mediated immune responses.[73,75,76] Protection mediated via TH1 cells may involve interferon-γ-mediated enhancement of the antimicrobial activity of macrophages, especially mannose receptor-mediated phagocytosis.[77] In the case of TH17 cells, production of the cytokine IL-17A leads to the recruitment of neutrophils and increased pneumococcal killing by these cells.[73] Following initial partial control of colonization by innate neutrophil-mediated mechanisms, recent evidence favors a primary role for Th17 cells in the recruitment of monocytes/macrophages to mucosal surfaces, resulting in the clearance of primary bacterial colonization.[73,78]

In summary, entry of the *Pneumococcus* into the nasopharynx has several possible outcomes: i) eradication by innate/adaptive host defences; ii) a carrier state in which the bacteria and host coexist in relative harmony; iii) a state of persistence in which bacteria are encased in biofilm, either extracellularly or intracellularly following adherence to, and invasion of epithelial cells, enabling evasion of host defenses (this could also be considered as being a chronic infection); and iv) acute infection. In the case of carrier and persistence states, the bacterial pathogen, seemingly subdued, may strike when host defences are transiently compromised, as may occur during infection with influenza or other respiratory viruses.

DIAGNOSTIC TESTING

A vast number of studies have been undertaken over many years to assess the value of the various microbiological techniques that are available for the diagnosis of likely microbial etiology in patients with CAP. Among more commonly used investigations currently available are sputum examination by Gram's stain and culture and pneumococcal antigen detection, blood for culture and serological testing, and urine for legionella and pneumococcal antigen detection. Much less frequently used are invasive techniques such as fiber-optic bronchoscopy. While some studies have indicated that there is good diagnostic yield from many of these tests, including simple sputum examination,[79,80] others have suggested that routine initial sputum examination is of little value, particularly in non-severely ill cases,[81] such that this investigation is frequently not used even in hospitalized cases.[82] One technique that has significantly improved the rapid sputum diagnosis of pneumococcal pneumonia is Real-Time Quantitative Polymerase Chain Reaction (RQ-PCR), which appears to be particularly useful in patients who have already received antibiotics.[83] While isolation of microorganisms from blood culture is considered a "gold standard" for the diagnosis of likely etiology of CAP, a number of studies have indicated that there is a low yield from blood cultures and that even a positive result does not frequently result in a change in antibiotic management, or subsequent cost saving, particularly in non-severely ill cases.[84-87] One study documented that the yield of blood cultures increased as the severity of infection increased, as measured by the Pneumonia Severity Index (PSI), as did the likelihood of blood cultures changing antibiotic therapy. Rapid urine antigen tests for the detection of *S. pneumoniae* and *Legionella pneumophila* serogroup 1 infection are very useful for indicating these pathogens as likely cause of CAP in adults.[88] These tests have good sensitivity and specificity, but are expensive and in many guidelines, both in developed and developing countries, are not routinely recommended, but are reserved for special cases, such as severely ill patients requiring Intensive Care Unit (ICU) admission.[89,90] Other serological testing for so-called atypical pathogens is not routinely recommended.[89] In HIV infected patients, additional microbiological testing for *Pneumocystis jirovecii* and *Mycobacterium tuberculosis* may need to be undertaken.[89]

There is considerable debate about the routine need for a chest radiograph in all patients with CAP, particularly in cases not apparently severe enough to require hospital admission. Some have suggested that it remains an "essential initial test" in the diagnosis of CAP that is recommended in most guidelines, certainly for hospitalized cases.[89-91] There are studies, however, indicating that the admission chest radiograph lacks sensitivity and that it may not demonstrate abnormalities initially in some 21% of patients.[92] The chest radiograph is unhelpful in suggesting likely microbial etiology and is performed in order to confirm the presence of pneumonia, to delineate the extent of the pulmonary involvement, as an indicator of the severity of infection, to delineate the presence of underlying disorders and to determine the presence of any complications.[89,90,93] The assessment of oxygenation is recommended in both outpatients and inpatients and can be undertaken by pulse oximetry, particularly in outpatients or by arterial blood gas analysis.[94] Routine hematological and biochemical testing do not help to determine likely etiology, but will assist in the assessment of comorbid illness, and influence decisions regarding need for hospitalization, severity of infections and choice and dosage of initial, empiric antimicrobial therapy.[89] Table 53.3 indicates the diagnostic testing that is commonly recommended in patients with CAP. These investigations are particularly recommended in high-risk cases, in those patients with underlying comorbid illnesses and in those with more severe infections.[89]

TABLE 53.3: Diagnostic testing recommended for more severely ill, hospitalized patients with community-acquired pneumonia

- Chest radiograph
- Sputum Gram stain and culture
- Blood cultures
- Blood gases (or assessment of oxygenation by pulse oximetry)
- Routine hematology and biochemistry
- Rapid urine antigen testing for *S. pneumoniae* and *Legionella* spp. serogroup 1
- Thoracentesis for pleural effusions

PROGNOSIS

The outcome of CAP is influenced by a number of factors, including host factors, bacterial factors and antibiotic factors.[95] In a study of overall factors influencing the outcome of adult patients with CAP in New Delhi, India, factors such as old age, history of smoking, presence of COPD, high blood urea, low serum albumin and development of septic shock were associated with a higher risk of complications and a poorer prognosis.[96] In addition, older patients with a poor prognosis had a greater duration of symptoms and a poor neutrophil response to the infection.

Host Factors Including the Severity of Infection

Among the host factors, older age, the presence of underlying comorbid illness and various genetic characteristics of the host, all are potentially associated with the increased risk of pneumonia, as well as a worse outcome.[95] Severity of illness on its own may impact negatively on pneumonia outcome, even in the absence of any of these other risk factors.[3,95,97] Severity of illness assessment is therefore important not only because it gives an indication as to the likely outcome of the patient with CAP, but because it dictates the appropriate site of care of these patients, the extent of the microbiological work-up needed and the choice of initial empirical antimicrobial chemotherapy.[3,95,97] A number of severity-of-illness indices and various scoring systems have been developed to assist in severity assessment, among which the PSI and the CURB-65 score (derived from the British Thoracic Society rules) are the most commonly used.[97] The PSI score comprises of 20 variables that include details of demographic characteristics, comorbidity, clinical features and results of laboratory and radiographic data.[98] The CURB-65 includes variables, indicative of severity including mental confusion (abbreviated mental test score ≤ 8), raised urea (>7 mmol/l), rapid respiratory rate (≥ 30 breaths/min), low blood pressure (systolic <90 mm Hg, diastolic ≤ 60 mm Hg) and age

TABLE 53.4: Parameters used to determine the CURB-65 severity of illness score[¶]

C = Confusion
U = Raised urea (>7 mmol/l)
R = Rapid respiratory rate (≥30 breaths/minute)
B = Low blood pressure (systolic <90 mm Hg, diastolic ≤60 mm Hg)
65 = Age ≥65 years

[¶] A point is assigned for each parameter, when present. Patients with a score of 0 or 1 have a mild pneumonia associated with a low mortality, those with a score of 2 have a moderate pneumonia with an intermediate mortality and those with a score of 3 or more have severe pneumonia associated with a high mortality.

≥65 years).[99] The PSI was developed primarily to identify low-risk patients who could safely be managed at home, whereas the CURB-65 score was developed to identify patients with severe CAP at high risk of mortality.[100,101] A modification of the latter score, the CRB-65 score has also been developed and studied with the advantage that it does not require the measurement of blood urea levels. It has been found to have similar accuracy to the CURB-65 score. A number of guidelines on the management of pneumonia, particularly from the developing world, have primarily recommended the use of the CURB-65 or CRB-65 as the severity scoring index of choice because of its simplicity, immediate applicability and ease of use, combined with an accuracy that is similar to that of more complicated systems such as the PSI.[89,90,102] The parameters that make up the CURB-65 score are indicated in Table 53.4.

Several other severity scores and indices have been developed and/or studied, particularly for use in predicting the outcome and need for ICU admission among severely ill cases[101,103,104], as well as in the subset of patients with pneumococcal CAP.[105,106] It is important to remember that these scoring systems have a number of limitations, including lack of inclusion of certain social factors and other clinical conditions that may impact on outcome. Thus, while each scoring system has its own individual strengths and weaknesses, none of them is able to replace sound clinical judgment of the attending physician.[101]

Bacterial Factors

Among the bacterial factors that may impact on the outcome of pneumonia, are the nature of the infecting microorganism, its associated virulence factors and its susceptibility to commonly prescribed antibiotics.[95] Significant consideration also needs to be given to the potential impact of antibiotic resistance, particularly pneumococcal resistance to beta-lactam agents on the outcome of pneumonia.[1,95,107-110] While much has been published on this subject, it does appear, overall, that the current levels of beta-lactam resistance among pneumococcal isolates are such that if appropriate beta-lactam agents are used in appropriate dosages, resistance should not impact negatively on the outcome of respiratory tract infections.[107,108,110] This is further supported by the fact that in January 2008, the Clinical and Laboratory Standards Institute (CLSI) revised its pneumococcal susceptibility breakpoints for penicillin for non-meningeal infections being treated with parenteral antibiotics, supported by a careful consideration of microbiological, pharmacokinetic/pharmacodynamic and clinical data.[111] Breakpoints are now much higher with isolates with a MIC of equal to or less than 2 µg/ml being considered susceptible, those with a MIC of 4 mg/ml being considered intermediately succeptible and those with a MIC equal to or greater than 8 mg/ml being considered resistant.

The situation is less clear-cut in the case of macrolide antibiotics, which have received much less attention, but it does appear that when these agents are used on their own, particularly in the presence of high-level macrolide resistance, failure of therapy, including breakthrough bacteremias might well occur.[95,112] With regard to pneumococcal fluoroquinolone resistance, while it is well recognized that phenotypic resistance with the presence of multiple mutations in the quinolone resistance-determining regions (QRDR) of parC and gyrA is known to be of clinical significance, what is not commonly appreciated is that first-step mutations in these regions, not producing MIC-defining phenotypic resistance, can easily mutate to the further levels of fluoroquinolone nonsusceptibility and lead to clinical failure.[112-114] However, the prevalence of such first-step mutants among populations of susceptible pneumococcal isolates is not reported and is therefore unknown in most parts of the world.

Of considerable concern internationally is the fact that there are very few new antibiotics in the developmental pipeline that would be available to combat infections due to highly resistant microorganisms, should these become more widespread.[115,116] While other adjunctive strategies are being studied for use, together with antibiotics, to improve the outcome of severely ill patients with CAP, it still remains true that the mainstay of therapy of such infections will always be effective antibiotic therapy.[97,117-119]

Antibiotic Factors

Among the antibiotic factors, choice of agent, dosage and duration of therapy and time to the initiation of antibiotics from the time of presentation of patients to hospital, all potentially play a role in the outcome of pneumonia.[3] Importantly, new strategies recommended for antibiotic management, for example, the use of combination antibiotic therapy in more severely ill hospitalized cases with pneumonia, including the subset of patients with bacteremic pneumococcal infections, have been said to have a positive impact on pneumonia outcomes.[43,95,120,121] The most commonly used combination therapy, which has been shown to be beneficial, is the addition of a macrolide to standard beta-lactam therapy; although benefit has also been shown with other combinations.[95,120] A number of questions still remain with regard to combination therapy, including an understanding of the reason(s) that some studies appear to indicate no beneficial effect of combination therapy on the pneumonia case-fatality rate.[122] Alternatively, should combination truly be shown to be beneficial, clarification is needed regarding which combination(s) are best,[123] as well as the exact mechanism(s) by which combination therapy may prove to be beneficial.[95,120] One of the reasons suggested for the benefit of combination therapy is that it may be associated with the addition to the beta-lactam agent of an antibiotic effective against so-called atypical pathogens (i.e. a macrolide, azalide, ketolide, tetracycline, or fluoroquinolone). Interestingly, a recent study investigated the outcome of bacteremic pneumonia in relationship to initial antibiotic therapy and although the investigation confirmed that the use of an agent active against atypical pathogens was independently associated with decreased 30-day mortality, further analysis suggested that this benefit was limited to the use of macrolides and not fluoroquinolones or tetracyclines.[124] Furthermore, an additional study documented that macrolide use was associated with a decreased mortality in patients with severe sepsis due to pneumonia, including the subset of patients infected with macrolide-resistant pathogens.[125] The role of macrolides in therapy is discussed further below (adjunctive therapy).

Guidelines for the Management of Pneumonia

As a part of the global strategy, a number of national and international guidelines have been developed describing the optimal management of patients with CAP, with the intention of improving the care and outcome of these patients.[89,104,126,127] However, consensus on the optimal management of lower respiratory tract infections, particularly with regard to antibiotic therapy, has not been attained in the various guideline documents.[126] Part of the reason for the differences in the guideline recommendations may relate to local factors, such as different patient populations, causative microorganisms, antimicrobial resistance patterns and availability of resources, together with differences in the interpretation of existing data by the guideline committee members.[127] Certainly, until more recently, there has been a relative lack of a robust evidence base for several aspects of the guideline recommendations.[127] Many of the newer guidelines are being informed by the various studies of CAP and in particular, very large multicenter, international, collaborative studies of CAP being conducted currently, which are able to recruit large number of cases throughout the world.[128]

Yet another issue is whether there is general adherence to the guideline recommendations and or whether adherence has any impact on the outcome of patients with CAP.[117,129,130] Some studies have suggested that compliance with guidelines may be associated with better outcome and lower costs of management in patients with CAP.[117,126,131,132] One recent study from Italy, conducted in three phases, documented an advantage for compliant versus noncompliant therapy, both in terms of failure rate (OR 0.74: 95% CI 0.60-0.90; p = 0.004) and mortality (OR 0.77: 95% CI 0.56-1.04; p = 0.082).[130] This was despite relatively low compliance with the national guideline recommendations, which did not increase substantially even after the guideline implementation phase of the study (from 33 to 44% compliance). These findings prompted the authors to suggest that there was need for a more aggressive and proactive approach to ensure guideline compliance. A single study from South Africa has documented very poor adherence to the local CAP Guideline, with the number of patients receiving compliant therapy being too low to confirm a clinical benefit from guideline adherence.[129]

TREATMENT OF COMMUNITY-ACQUIRED PNEUMONIA

Antibiotic Treatment

The mainstay of therapy for CAP is the use of antibiotics. Empirical antibiotic therapy should particularly take into consideration severity of illness, likely etiological agent, resistance patterns among commonly identified pathogens, especially *S. pneumoniae* and underlying comorbidities.[1] An additional consideration in the developing world is the cost of the individual drugs.[133] Antibiotic therapy should be commenced as soon as possible after diagnosis. With regard to outpatient therapy, a recent Cochrane review concluded that currently available evidence from randomized controlled trials was insufficient to make any evidence based recommendations for antibiotic choice in the ambulatory setting.[134] A number of guidelines, both in developed and developing worlds, recommends the use of oral therapy with amoxicillin for outpatients.[89,102] Macrolide monotherapy has been suggested as an alternative, particularly for patients allergic to penicillin, but this recommendation would need to take into consideration local susceptibility patterns to macrolides. Other oral agents, such as amoxicillin/clavulanate, second-generation cephalosporins and fluoroquinolones can be used, but are more expensive and are generally reserved for elderly patients, for those cases that are more severely ill and those that have underlying comorbid conditions, or that have failed initial therapy.

For more severely ill, hospitalized cases, most guidelines recommend the use of a beta-lactam/macrolide combination or monotherapy with a respiratory fluoroquinolone.[89,102]

For cases requiring ICU admission, additional agents are recommended; for example, the addition of an aminoglycoside to a beta-lactam/macrolide combination to provide additional cover for suspected gram-negative infection.[89,104] If a fluoroquinolone is used for an ICU patient, it is commonly recommended that it should be combined with another agent such as beta-lactam.[89,104]

Caution must be exercised with the routine use of fluoroquinolone monotherapy for patients presenting with CAP in regions where tuberculosis is endemic, since such cases may actually be infected with *M. tuberculosis* (Table 53.1), for which fluoroquinolones have excellent in vitro activity. Studies have indicated that in this situation, fluoroquinolone use may be associated with delay in the diagnosis of tuberculosis with the masking of this infection.[135,136] Consequent to this is the potential for patient morbidity and even mortality, as well as ongoing secondary transmission. Furthermore, there are additional concerns that fluoroquinolone monotherapy used in this situation may result in fluoroquinolone-resistant tuberculosis, although studies have suggested that this really only occurs in patients who have been exposed to multiple previous courses of fluoroquinolones.[137,138]

Supportive and Adjunctive Therapies

General support for patients with CAP includes attention to nutrition and hydration, analgesia and supplemental oxygen. A number of adjunctive therapies have been studied, particularly in severely ill patients, including those in the intensive care unit setting, in an attempt to further decrease the ongoing high mortality among these patients.[139] The two agents that appear to be most promising are the macrolide group of antibiotics and corticosteroids. The role of macrolides in the therapy of pneumonia has been fully described above (antibiotic factors). The reason they are included as possible adjunctive therapy is that many believe that the benefit of adding a macrolide to standard beta-lactam therapy may not be related to their antimicrobial activity, but rather to the considerable anti-inflammatory, immunomodulatory activities that the macrolide group of antibiotics possess translating not only into beneficial effects in the human host, but also attenuation of the virulence factors of bacteria, such as the pneumococcus, even at low, sub-minimum inhibitory concentrations that do not kill the microorganisms.[121,140-143]

With regard to corticosteroids, while two more recent systematic reviews[144,145] came to somewhat differing views as whether to recommend the routine use of corticosteroids in patients with CAP, there are clearly a number of studies documenting benefit of their use in hospitalized patients and/or cases with severe CAP[139,146-148] with some documenting a decrease in mortality and others a more rapid resolution of symptoms and a reduced duration of intravenous antibiotic therapy. There is also good scientific evidence to understand possible mechanisms by which corticosteroids may have benefit, considering their significant effects on inflammatory responses.[139] Corticosteroid use is most commonly recommended in patients with severe CAP in association with septic shock.

Thus, while some suggest that final recommendations regarding routine macrolide and/or corticosteroids use should await comprehensive randomized control trials, most clinicians would consider using them in severely ill cases with CAP.[119,120]

PREVENTION OF INFECTION—VACCINATION

An important aspect to consider in the overall control of CAP, and in particular pneumococcal pneumonia, is the prevention of infection using vaccination. Currently two pneumococcal vaccines are commercially available, namely the Polyvalent Polysaccharide Vaccine (PPV), used predominantly in adults and the Pneumococcal Conjugate Vaccine (PCV), used predominantly in children.[149,150] While there remains considerable debate as to the efficacy of the PPV, meta-analysis certainly supports the evidence for its use in the prevention of invasive pneumococcal disease in adults.[150] Evidence is considered by some to be somewhat less compelling with respect to efficacy in adults with chronic illness and in its routine use to prevent all causes of pneumonia or reduce overall pneumonia mortality.[150] However, others have suggested that the evidence points to a lower, but not insignificant protective effect, even in nonbacteremic pneumonia, such that this should not preclude the more widespread use of the vaccine.[151] Furthermore, recent studies also point to a significant beneficial effect in preventing pneumococcal pneumonia and decreasing disease severity, even in the vaccinated elderly.[151] A lower overall rate of pneumonia and improved outcome have also been seen in HIV-infected adults who have received PPV previously.[152,153]

Even more compelling is the evidence for the use of the PCV in the safe prevention of pneumococcal infection in children in both low income and industrialized countries, including HIV-infected individuals, meeting international criteria of cost-effectiveness even for lower income countries.[149,154] For this reason, the vaccine is recommended by the World Health Organization for inclusion in national vaccination programs in countries such as South Africa and elsewhere. Interestingly, in some of the studies, the PCV has been effective in lowering the rate of invasive pneumococcal disease not only in vaccinated children, particularly those below the age of 2 years, but also in non-vaccinated children and even in adults and the elderly in the community.[155] As such the vaccine appears to have both direct immune benefits in those vaccinated, as well as indirect "herd immunity" effects.

Influenza vaccination is also recommended in many CAP guidelines, even in the developing world.[89,90] While influenza vaccine may be administered to any individual wishing to reduce the risk of being infected with influenza, systematic annual vaccination is routinely recommended for individuals at high-risk of being infected with influenza and/or experiencing complications, such as pneumonia, from this infection.[90] It is also recommended that individuals that can transmit influenza to high-risk cases, such as health-care workers, should be immunized yearly.[94]

CONCLUSION

It has been stated that the mortality of CAP remains substantial in both the developed and developing worlds, despite all recent advances in medicine, including the availability of potent antimicrobial therapy and even the establishment of intensive care unit facilities. A number of questions and challenges still remain with regard to a full understanding of the nature of CAP and its optimal management that require continuing research.[100]

Pulmonary Fungal Infections

Arunaloke Chakrabarti

INTRODUCTION

Fungi rarely cause respiratory tract infection in the healthy population, except for the dimorphic fungi. In contrast, fungal infections of the respiratory tract are important causes of morbidity and mortality in immunocompromised patients; the range of people at risk of these infections has been expanding over the last two decades with the increased use of immunosuppressive agents in the treatment of malignancies and autoimmune disorders, the growing number of transplant recipients and due to the aging of the population.[1,2] Fortunately, in some of those patient groups, a downwards trend of the fungal infections related mortality has been observed in the last decade with the improvement in medical care.[3,4] However, parallel to this positive development, the spectrum of patients at risk for respiratory fungal infections is also expanding.[2,5] Pulmonary mycoses can either be the primary presentation of the disease or be a manifestation of disseminated fungal infections.

EPIDEMIOLOGY

The susceptible population for pulmonary fungal infections can be divided in two groups: Classical and newly recognized risk groups (Table 54.1). The risk factors for pulmonary mycoses in developing countries appear similar to the developed world; though certain differences are observed due to local epidemiology, including patient characteristics, cultural habitat and patient care practices.[6-8] Sub-optimum hospital care practice in the economically deprived groups and increasing medical interventions, including transplantations in the prosperous group, have led to an increase in the number of invasive fungal respiratory tract infections in both the groups. Further, the large number of untrained health care providers, misuse of steroids, intravenous drug abuse and availability of spurious infusion sets are possible additional risk factors for pulmonary mycoses in these countries. The number of persons at risk of pulmonary mycoses in developing countries is staggering.[6-8]

The growing incidence of pulmonary mycoses, which are linked to classical risk factors is in the range of 3 to 56% (Table 54.2).[9,10] The patients usually have significant neutropenia (<500 neutrophil/µl for >10d) as risk factor.

TABLE 54.1: Susceptible population for fungal respiratory tract infection

Classical risk groups:
- Cytotoxic chemotherapy for neoplastic disease
- Hematopoietic Stem Cell Transplantation (HSCT)
- Severe AIDS (CD4 cell count <100)
- Immunosuppressive therapy in autoimmune diseases
- Other transplantations
- Aging population

Newly recognized risk groups:
- Intensive care unit stay
- Chronic obstructive lung disease
- Recipients of low dose of steroids
- Cirrhotic patients
- Iron overload
- Poorly controlled diabetic patients
- Sepsis associated with immunoprophylaxis
- Malnutrition
- Moderate to severe renal or hepatic impairment

TABLE 54.2: Incidence of fungal pneumonias in classical risk factor groups (modified from Pound et al [9])

Population	*Incidence*	*Fungal pathogen*
HIV infected patients	Not known (30%-45% *Cryptococcus)*	*Cryptococcus, Aspergillus, Coccidioides, Histoplasma, Blastomyces*
Bone marrow transplant recipients		
— Allogenic	12%-56%	*Aspergillus, Scedosporium, Fusarium, Candida*
— Autologous	rare	
Solid organ transplant recipients		
— Liver	Almost 35%	*Aspergillus, Cryptococcus*
— Lung	14%-35%	*Aspergillus, Cryptococcus, Candida*
— Heart	3%-10%	*Aspergillus, Candida*
— Kidney	Not known	*Cryptococcus, Aspergillus, Zygomycetes*

The rise in number of pulmonary mycoses is partly due to increased indications of hematological transplantation procedures in recent years and evolving solid organ transplantation practices. Additionally, explosion in the number of novel biological immunesuppressant agents and widespread use of antimicrobial prophylactic regimens, including fluconazole prophylaxis, render the host at greater risk of fungal colonization and infection.[11] Other risk factors for those individuals include poor graft function, hepatic failure before transplantation, dialysis requirement, use of OKT3 antibodies, cytomegalovirus infection and thrombocytopenia.[11] Among solid organ transplant recipients, lung and liver transplant recipients appear to have a higher incidence of pulmonary mycoses (Table 54.2). In lung transplant, apart from immunosuppressant use, impairment of lymphatic drainage, blunted cough reflex and defective mucociliary clearance contribute to fungal growth in the transplanted lung.[12] Among Human Immunodeficiency Virus (HIV) infected patients, pulmonary mycoses, such as *Pneumocystis* pneumonia and *Cryptococcal* infection, are associated with peripheral CD4 count of less than 200 cells/µl. Although *Aspergillus* pneumonia occasionally occurs in advanced HIV infection, this opportunistic complication is generally uncommon.[11]

Other than classical risk factors, prolonged stay in Intensive Care Unit (ICU), corticosteroid (>4 week) treatment, Chronic Obstructive Pulmonary Disease (COPD), liver cirrhosis, individuals with systemic inflammatory disease requiring immunosuppressive therapy, poorly controlled diabetes and iron overload (Table 54.1) are newly recognized risk factors for pulmonary mycoses.[13] The incidence of pulmonary mycoses in ICUs of developing countries is expected to be higher since cofactors (multiple intravenous lines, tracheostomy, endotracheal intubation, other invasive procedures, prolonged corticosteroid and antibiotic therapy) in ICUs are either higher in numbers or misused more in developing countries due to suboptimal protocol adherence by the ICU staff. Chronic obstructive pulmonary disease is an emerging risk factor. In a recent review of 65 cases, invasive pulmonary aspergillosis was reported as a serious emerging infection in patients with COPD. The majority of the patients had advanced COPD and/or on systemic corticosteroid therapy.[14] The reports of pulmonary mycoses in solid tumor are rare. In a large series from China, approximately 3% lung cancer patients had pulmonary aspergillosis. On univariate analysis, chemotherapy, steroid use and stage IV disease were found to be the significant risk factors; on multivariate analysis only stage IV disease was the significant risk factor. Neutropenia and corticosteroid therapy correlated statistically with pulmonary aspergillosis in patients who died.[15]

AGENTS RESPONSIBLE

Although many fungi can cause respiratory infections (Table 54.3), aspergillosis is the greatest challenge in patients with prolonged neutropenia, recipients of hematopoietic stem cell transplants or solid organ transplants, and patients with advanced Acquired Immunodeficiency Syndrome (AIDS) or chronic granulomatous disease. Host factors govern both the risk and clinicopathological features of invasive aspergillosis.[16,17] Other filamentous fungi, such as *Fusarium* spp., *Pseudallescheria boydii* and *Zygomycetes* are reported with increasing frequency in patients with quantitative or qualitative defects in neutrophils.[2] Pulmonary zygomycosis is also reported in patients with uncontrolled diabetes in India.[18] The clinical presentation, radiological features and histological appearance of pulmonary

- *Pneumocystis jiroveci*
- Rarely yeasts (*Cryptococcus*, *Candida*, *Trichosporon*)
- Rarely black fungi (*Cladophialophora boppii*)

infections due to *Fusarium* spp. and *Pseudallescheria boydii* have marked resemblance to *Aspergillus* infections leading to frequent misidentification.[19] Other than these opportunistic fungal infections, endemic mycoses, including those due to *Histoplasma capsulatum, Coccidioides immitis* and *Penicillium marneffei* have increased in frequency in immunocompromised hosts in restricted geographic regions.[2] A rare case of fatal pulmonary sporotrichosis caused *S. schenckii var luriei* was reported from India.[20] *Pneumocystis jiroveci* infection had frequently been reported in patients with AIDS, but recent data showed a sharp decline in incidence after the introduction of chemoprophylaxis and tri-drug regimen in those patients.[21] Yeasts are rarely reported in respiratory tract infections.[2] Among yeasts, cryptococcal respiratory tract infections are seen more consistently. Though deep seated infections due to black mycelial fungi are increasingly reported in recent years, they rarely cause pulmonary infections. A very rare case of pulmonary *Cladophialophora boppii* infection has been reported recently in lung transplant recipient.[22]

Aspergillosis

Pulmonary aspergillosis may be classified as allergic, saprophytic and invasive (Table 54.3).

Allergic Alveolitis

The common epidemiological setting of extrinsic allergic alveolitis due to *Aspergillus* is repeated exposure in non-atopic workers to *Aspergillus* antigen in moldy hay or grain, hence, the terms “farmer’s lung” or “malt worker’s lung.” Symptoms include cough, dyspnea, fever, chills and myalgias within eight hours of exposure. A chest radiograph may reveal interstitial infiltrates. Relief of symptoms has been observed within 48 hours, while away from exposure. However, repeated exposure may lead to intractable pulmonary fibrosis.[2]

Allergic Bronchopulmonary Aspergillosis (ABPA)

Allergic bronchopulmonary aspergillosis is an allergic pulmonary disorder caused by allergic response to *Aspergillus* hyphae without direct tissue invasion by the organism. It manifests as chronic asthma, recurrent pulmonary infiltrates and bronchiectasis.[23,24] Bronchospasm in this process is thought to be mediated by an IgE (type I reaction) mediated hypersensitivity, whereas the bronchial and peribronchial inflammation appears to be induced by immune complex formation (Type III reaction) and eosinophil-rich inflammatory cell responses due to Type IV hypersensitivity. The prevalence of ABPA is claimed as 1% to 2% in patients with asthma and 2% to 15% in patients with cystic fibrosis.[25] In a recent study of patients attending chest clinic in North India, 27% of asthmatics met criteria for ABPA[26] (See Chapter 75 for details). Spectrum of *Aspergillus* pulmonary infections are given in Table 54.4.

Eosinophil-related Fungal Rhinosinusitis

Several types of sinus diseases have been attributed to the presence of fungal organisms in the nasal and sinus cavities. The incidence of Chronic Rhinosinusitis (CRS) and Fungal Rhinosinusitis (FRS) has increased over the

last decade. Confusion exists regarding classification, the most accepted classification divides FRS into invasive and noninvasive diseases based on histopathological evidence of tissue invasion by fungi. The invasive diseases include acute invasive, granulomatous invasive and chronic invasive FRS. The noninvasive diseases include localized fungal colonization, fungal ball and eosinophil-related FRS that includes Allergic Fungal Rhinosinusitis (AFRS).[27] The existence of allergic disease to fungi in nasal and paranasal sinus cavities was recognized about three decades ago. Allergic fungal rhinosinusitis is considered as a non-tissue invasive fungal process, representing an allergic/hypersensitivity response to the presence of extramucosal fungi within the sinus cavity, possibly akin to ABPA.[28] In western world, dematiaceous fungi, including *Alternaria sp.;* and in Middle East, Sudan and India, *Aspergillus flavus* are commonly isolated from such patients.[27-29]

It is believed that fungal allergens elicit IgE-mediated allergic and possibly type III mediated mucosal inflammation in the absence of invasion in an atopic host. Moreover, when the sensitized individuals are exposed to an environment of high fungal content, symptoms of upper and/or lower airway hypersensitiveness increase significantly. Generalized sinonasal inflammation in combination with viscid allergic mucin effectively obstructs the normal drainage pathway. Fungi persist locally, stimulating locally destructive immune response. The process then extends to involve adjacent sinuses and may produce sinus expansion and bony erosion.[29] Although, the presentation of the disease is subtle, occasional dramatic presentations of the disease in the form of acute visual loss, gross facial dysmorphia or complete nasal obstruction has been observed.

To diagnose AFRS, Bent and Kuhn proposed five diagnostic criteria:[30] Type I hypersensitivity, nasal polyposis, characteristic findings on Computed Tomography (CT) scan, presence of fungi on direct microscopy or culture and allergic mucin containing fungal elements without tissue invasion. Although the detection of fungi in allergic mucin is considered important, hyphae may be sparse in sinus content and take considerable time to visualize with the commonly used stains. This has led to confusion in the categorization of this entity, especially with the description of Eosinophilic Mucin Rhinosinusitis (EMRS).[31]

It was speculated that EMRS is a systemic disease with the dysregulation of immunological control where eosinophilic mucin could be present without the presence of fungi.[31] The definition of AFRS has faced a greater challenge with the demonstration of fungi in eosinophilic mucin independently of Type-I hypersensitivity in most of the cases of CRS. Ponikau et al. proposed a new term for this condition, namely Eosinophilic Fungal Rhinosinusitis (EFRS) to reflect the striking role of eosinophil.[32] It is proposed that high levels of Major Basic Protein (MBP) is released from eosinophils in the mucus of the patients with CRS and postulated that MBP damages the nasal epithelium from the luminal side permitting secondary bacterial infections on the damaged epithelium.[33]

Saprophytic Aspergillosis

Saprophytic or colonizing forms of aspergillosis develop in an existing pulmonary cavity, caused by old tuberculosis, emphysema or carcinoma. Children with cystic fibrosis and bronchiectasis may also have saprophytic involvement of the airway due to *Aspergillus* spp. The mass of hyphae amidst a proteinaceous matrix is called as aspergilloma. However, filamentous fungi other than *Aspergillus*, such as *Pseudallescheria boydii* and *Zygomycetes*, may also cause intracavitary fungus balls and simulate an aspergilloma.[34]

Similarly, fungal ball is described as the presence of noninvasive accumulation of dense conglomeration of fungal hyphae in one paranasal sinus cavity, usually maxillary sinus, although the disease may affect other sinuses or rarely multiple sinuses. Various terms, such as mycetoma, aspergilloma and chronic noninvasive granuloma have been used interchangeably to designate sinus fungal ball.[27] The disease is defined by the following criteria: A dense conglomeration of noninvasive hyphae in cheesy or clay-like materials within the sinus, radiological evidence of sinus opacification with or without radiographic heterogeneity, nonspecific chronic inflammation of the mucosa, no predominance of eosinophils or granuloma or allergic mucin and no histopathological evidence of fungal invasion of mucosa.[34] The disease has been found more commonly in middle-aged and elderly females.

Invasive Aspergillosis

Invasive aspergillosis occurs in patients with acquired (neoplastic diseases with persistent and profound neutropenia, receiving high doses of corticosteroids) or primary defects (chronic granulomatous disease and hyper-IgE syndrome) in neutrophil function. However, in recent years, even up to 41% of the cases of invasive aspergillosis were diagnosed in nonneutropenic patients, especially in patients with COPD, chronic liver disease, reactive airway disease and rheumatoid arthritis.[35]

Patients with HIV may develop invasive pulmonary aspergillosis when CD4 count falls less than 50 cells/cumm. Interestingly, invasive aspergillosis in patients with HIV infection remains restricted to pulmonary involvement only in majority number of cases. The various clinical manifestations of invasive aspergillosis include pneumonia, hemoptysis, invasion of contiguous intrathoracic structures and dissemination. These findings are reflection of angioinvasion, thrombosis and infarction and are not specific for aspergillosis and may be a manifestation of one of several opportunistic angioinvasive fungi like *Zygomycetes*, *Pseudallescheria boydii* and *Fusarium spp*. Fever may be the earliest manifestation of pulmonary aspergillosis.

Invasive pulmonary aspergillosis is highly prevalent in developing countries, especially in patients with malignancies and transplant recipients.[36-40] In the series of invasive aspergillosis, reported from tertiary care hospital in Thailand,[41] lung was involved in 68% cases followed by sinuses (17%), eyes (8%) and brain (5%). In an autopsy study of childhood pneumonia from Bangladesh, pulmonary aspergillosis was diagnosed in 3% of all pneumonias and 10% of necrotizing pneumonias.[42] Other than classical manifestations of pulmonary aspergillosis, certain uncommon clinical presentations have been observed in developing countries. Some of these observations include the development of invasive pulmonary aspergillosis in patients with colonizing aspergillosis (in tubercular cavity),[43, 44] ABPA or aspergilloma[45,46] and bronchial asthma.[15,43] Possibly long period of steroid therapy allowed fungal hyphae from cavitary lesion or localized mass lesion to invade lung parenchyma. Invasive pulmonary aspergillosis was also found to be associated with antineutrophil cytoplasmic antibodies positive vasculitis.[47,48] In a series of 157 patients with vasculitis, 7 (4.5%) developed invasive pulmonary aspergillosis; 2 had Wegener's granulomatosis and 5 had microscopic polyangiitis. Invasive pulmonary aspergillosis developed within 2 to 13 weeks of immunosuppressive therapy.[48]

Tracheobronchial Aspergillosis

The presence of *Aspergillus* spp. in the large airway may represent colonization or rarely, tracheobronchitis. Isolated invasive *Aspergillus* tracheobronchitis is mostly reported in patients with severely immunocompromised status due to transplantation or hematological malignancies or AIDS. Of note, 19 patients with isolated invasive *Aspergillus* tracheobronchitis were reported from China, who had impaired airway structures or defense functions rather than severely immunocompromised status. Only three (16%) patients had neutropenia. Malignancy (13 cases of solid tumor, 1 case of lymphoma) was the most common underlying disease. The disease could be classified into four different forms: Superficial infiltrative, full layer involvement, occlusion and mixed type.[49]

Chronic Necrotizing Pulmonary Aspergillosis

It is another subset of pulmonary aspergillosis. This indolent infection has been reported in elderly patients with COPD, inactive tuberculosis, pneumoconiosis or sarcoidosis. Subtle defects in systemic host defense due to malnutrition, alcoholism, diabetes mellitus or low-dose corticosteroids may also be evident. It is present as chronic refractory bronchopneumonia with fever, weight loss, cough, progressive infiltrates and evidence of invasive aspergillosis on biopsy. The infection may progress to cavitation and formation of an aspergilloma or may develop from an aspergilloma as the initial focus.[2]

Invasive Fungal Rhinosinusitis

As mentioned earlier, invasive FRS include acute invasive, granulomatous and chronic invasive FRS depending on host immune status, geographical region. Acute invasive FRS is described by a time course of less than four weeks with predominant vascular invasion occurring in patients with immunocompromised status. The histopathology demonstrates hyphal invasion of blood vessels, including carotid arteries and cavernous sinuses, vasculitis with thrombosis, hemorrhage, tissue infraction and acute neutrophilic infiltrates. Granulomatous invasive is described by a time course of less than 12 weeks with an enlarging mass in the cheek, orbit, nose and paranasal sinuses in immunocompetent hosts. Proptosis is often a prominent feature. The disease has primarily been seen in Sudan, India, Pakistan and Saudi Arabia.

Histopathologically, a granulomatous response is seen with considerable fibrosis. Hyphae are usually scanty and *A. flavus* is the primary agent isolated. Chronic invasive FRS is a slowly destructive process with a time course of less than 12 weeks that most commonly affects the ethmoid and sphenoid sinuses, but may involve any paranasal sinus. In contrast to granulomatous invasive FRS, the entity is characterized as dense accumulation of hyphae, occasional presence of vascular invasion, and sparse inflammatory reaction in association with the involvement of local structures. The disease is usually associated with AIDS, diabetes mellitus and corticosteroid treatment. *A. fumigatus* is commonly isolated from such patients.[27,29]

Zygomycosis

It is an increasingly reported polymorphic disease caused by members of the class *Zygomycetes*. The most common sites of zygomycosis are the rhinocerebral area (39%), lungs (24%) and skin (19%).[17] Pulmonary zygomycosis is most frequently observed in granulocytopenic and corticosteroid treated patients. The patients with advance AIDS are also at risk. The epidemiology of zygomycosis seems to be different between developed and developing countries. In developed countries, the disease is still a rare finding and mostly seen in patients with hematological malignancies undergoing chemotherapy, in bone marrow transplant recipients and as breakthrough infection in patients receiving voriconazole therapy or prophylaxis. However, in developing counties like India, the number of zygomycosis cases seems to be on the rise, occurring commonly in patients with uncontrolled diabetes. The number of cases with uncontrolled diabetes is so overwhelming that the other risk factors are overshadowed.[2,18,50,51]

Most of the *Zygomycetes,* causing respiratory infections in immunocompromised or debilitated hosts have a high propensity for thrombotic invasion of blood vessels, for causing a rapidly evolving clinical course, high mortality and a relative resistance to antifungal therapy. Pulmonary zygomycosis may have a wide variety of disease manifestations, including solitary nodular lesions, lobar involvement, and cavitary or disseminated form. Infiltrates or mass lesions without any specific lobar predilections are common findings. Pulmonary consolidation and cavitations are seen less frequently, though in a series from India 23% had cavitary lesions.[52] Recently, two cases of pulmonary cavitary zygomycosis due to very rare species, *Rhizopus homothallicus* have been reported.[53] It is suggested that such cavities represent the liquefaction of pulmonary infarcts. Antemortem diagnosis of pulmonary zygomycosis is difficult due to the lack of specific symptoms and signs and large numbers (44% to 100%) of cases are diagnosed postmortem. Increased awareness may improve the proportion of cases with antemortem diagnosis. Open lung biopsy, surgical extirpation and needle aspiration under image guidance provide better results.[52]

Fusarium and Scedosporium Infections

Over the past two decades, *Fusarium spp*. and *Scedosporium apiospermum* or *Pseudallescheria boydii* (sexual stage) are emerging pathogens, especially in patients with hematological malignancies undergoing chemotherapy and bone marrow transplant recipients. The pulmonary infections caused by both agents are indistinguishable many times from that caused by *Aspergillus spp*. The organisms in tissue also resemble *Aspergillus spp*., having angular, septate dichotomously branching hyphae.[2,54,55]

Fusarium solani, Fusarium oxysporum, Fusarium moniliforme and *Fusarium chlamydosporum* are the commonly isolated agents from patients with invasive *Fusarium* infection. Though invasive *Fusarium* infections produce pulmonary disease similar to that of invasive aspergillosis, pulmonary infiltrates, cutaneous lesions and positive blood culture and sinusitis characterize it. Biopsy of cutaneous lesion and advanced blood culture detection system, such as lysis centrifugation help in the diagnosis of disseminated fusariosis.[54]

Scedosporium spp. causes sinusitis, pneumonia and disseminated infections in immunocompromised hosts and fungal ball in immunocompetent patients. Pneumonia due to *Scedosporium apiospermum* is clinically indistinguishable from that due to *Aspergillus spp*. Other *Scedosporium* species, *S. prolificans* can also cause pneumonia in immunocompromised host and is considered to be mere virulent and resistant to amphotericin B. Diagnostic approaches are similar to aspergillosis or zygomycotic infections. The organism in tissue resembles *Aspergillus spp*., as angular, septate dichotomously branching hyphae. The definitive microbiologic diagnosis is established by culture.[55] Blood culture may help in *S. prolificans* isolation.

Respiratory Infections due to Dimorphic Fungi

Dimorphic fungi, including *H. capsulatum, B. dermatitidis, Coccidioides immitis, Paracoccidioides brasiliensis, Penicillium marneffei* and rarely *Sporothrix schenckii* may cause respiratory tract infection. The dimorphic fungi do appear to follow a geographically defined endemic pattern of distribution. *Penicillium marneffei,* the fungus causing penicilliosis has its environmental niche is Southeast Asia only.[56-58] Histoplasmosis, though earlier considered uncommon in Asia-Pacific region, is increasingly reported in many countries, especially in patients with AIDS.[59,60] Autochthonous cases of blastomycosis are occasionally reported from this region,[61] coccidioidomycosis and paracoccidioidomycosis are rarely reported as imported disease.[62,63] Upon entry of the conidia of the dimorphic fungi into lower respiratory tract, the interaction of host defenses and various fungal factors determines the outcome of infection. The fungi are usually contained by alveolar macrophages, resulting in a localized granulomatous reaction. Calcification develops at the site of resolving granulomatous foci of *H. capsulatum* infection.

Histoplasmosis usually presents as mild insignificant self-limiting respiratory disease in the majority of patients from endemic areas. The clinical manifestations of histoplasmosis may be classified according to the site (pulmonary, extrapulmonary or disseminated), by duration of infection (acute, subacute and chronic) and by pattern of infection (primary vs reactivation). Acute primary pulmonary histoplasmosis may develop in a normal, immunocompetent host who is exposed to a heavy inoculum. Chronic cavitary pulmonary histoplasmosis is an indolent, but progressive respiratory infection of patients with underlying COPD. Acute progressive disease is seen in immunosuppressed host. Though the number of cases of acute progressive disseminated histoplasmosis has steadily increased in the Asia-Pacific region along with the rise of AIDS population, a large number of cases are diagnosed as chronic manifestations of disseminated histoplasmosis. These cases are diagnosed as the disease frequently presented with accessible mucocutaneous lesions that can be easily biopsied.[59,60].

It is not clear whether blastomycosis is endemic in any focus in the Asia-Pacific region as there are very few autochthonous cases reported from this region. Most of those cases were reported from India.[61] The fungus was isolated from pulmonary, cutaneous and cerebral lesions. The manifestations of *B. dermatitidis* infection are protean from an asymptomatic disease, a brief influenza like illness, self-limited localized pneumonia in immune competent patients, subacute to chronic respiratory illness and fulminant infection with adult respiratory distress syndrome. The infiltrates of pulmonary blastomycosis are nonspecific and appear as bronchopneumonia or segmental consolidation.

The manifestations of pulmonary penicilliosis are little known, it is believed that the infection has a striking resemblance to disseminated histoplasmosis in HIV infected patients. The recognition of penicilliosis is sometimes difficult, especially in the area where histoplasmosis is also endemic as both diseases present with fever, weight loss, cough, anemia, lymphadenopathy and hepatosplenomegaly. However, skin lesions are more common (60 to 85%) in penicilliosis. Even laboratory findings are similar between the two groups except hyperbilirubinemia, which is more common in the penicilliosis group.[64] HIV infected patients have a higher incidence of fungemia, higher antigen titer in *P. marneffei*-specific mannoprotein Mp1p enzyme-linked immunosorbent assay and low serum antibody level.[65] All those data indicate that only high degree of suspicion among clinicians treating HIV infected patients may help in the early diagnosis of penicilliosis cases, especially when many diseases mimic similar clinical presentations.

Pulmonary Cryptococcosis

The disease is frequently associated with disseminated infection especially in immunocompromised hosts. Cryptococcosis occurs in 0.3 to 5.3% (with a mean of 2.8%) of solid organ transplant recipients and 25 to 54% of transplant recipients with cryptococcosis have pulmonary disease and the disease is limited to the lungs in 6 to 33% cases.[66] In these patients fever, cough, dyspnoea and pleural pain are common initial manifestations. Interstitial infiltrates, miliary nodules, Acute Respiratory Distress Syndrome (ARDS), hilar lymphadenopathy and pleural effusion are typical radiographic features. Pulmonary cryptococcosis is relatively common and frequent finding in patients with AIDS. In an autopsy series of 8,421 South African Miners, with an estimated HIV prevalence of 24%, 589 cases (overall prevalence of 7%) of pulmonary cryptococcosis were identified. Antemortem diagnosis for cryptococcal meningitis was in 47% of these cases and for pulmonary cryptococcosis in 1.2% cases. The remaining 52% of those cases had been misdiagnosed as pulmonary tuberculosis.[67] Therefore, pulmonary cryptococcosis is often empirically treated as pulmonary tuberculosis.

Pulmonary Candidiasis

Pulmonary candidiasis may be a secondary process arising from hematogenous dissemination or rarely a primary bronchopneumonia. Primary *Candida* bronchopneumonia may be observed in severely debilitated, neutropenic patients and very low birth weight infants and usually associated with aspiration of oropharyngeal content. The diagnosis of pulmonary candidiasis is difficult because of nonspecific clinical and radiological presentation. The presence of *Candida* in the sputum, tracheal aspiration or Bronchoalveolar Lavage (BAL) mostly represents contamination from upper respiratory tract colonization. A definite diagnosis of *Candida* pneumonia requires histopathological proof of lung invasion. Children can also be affected by pulmonary allergic reaction due to *Candida* species.[68]

Pneumocystis Respiratory Tract Infection

Pneumocystis jiroveci, formerly known as *Pneumocystis carinii*, is a major cause of opportunistic infection in respiratory tract. Pneumonia caused by this organism is an AIDS defining illness having high morbidity and mortality. Though the infection rate has come down in HIV positive patients after antiretroviral therapy, patients with inherited or other acquired immune defects and those on immunosuppressive medications are vulnerable to *Pneumocystis* infection. Patients often present initially with a history of dry cough, fever, dyspnea and difficulty in deep inspiration. Physical examination reveals varying degree of tachypnea, tachycardia, cyanosis and rales. Chest radiographs often exhibit the pathognomonic bilateral diffuse infiltrates with a ground-glass appearance; however, focal infiltrates may also occasionally be seen.

Patients with AIDS and pneumocystis pneumonia have a significantly increased number of pneumocystis organisms and fewer neutrophils in their lungs than do patients with pneumocystis pneumonia in the absence of AIDS. The smaller number of neutrophils in patients with AIDS correlates with better oxygenation and survival as compared with pneumocystis pneumonia in patients without AIDS.[69,70] The mortality rate in AIDS with pneumocystis pneumonia is 10% to 20% during the initial infection, though the rate increases substantially with the need for mechanical ventilation.[71] The mortality rate in patients with pneumocystis pneumonia in the absence of AIDS is 30% to 60% depending on the population at risk, with a greater risk of death among patients with cancer than among patients undergoing transplantation or those with connective tissue disease.[69]

The gold standard for diagnosis is a lung biopsy, though BAL fluid and induced sputum is often utilized for the diagnosis. Gömöri methenamine silver, toluidine blue, calcofluor white stains, which stain pneumocystis cysts, are commonly used to identify P. jiroveci in those samples. Trophic forms can be detected with modified Papanicolaou, Wright-Giemsa, or Gram-Weigert stains. Monoclonal antibodies for detecting pneumocystis have a higher sensitivity and specificity in induced sputum samples than conventional stains have, but the difference is much less in BAL fluid.[72,73] In patients with pneumocystis pneumonia, serum lactate dehydrogenase usually rises, but it may reflect underlying lung injury rather than any specific marker of the disease. Lower level of plasma S-Adenosylmethionine was observed in patients with pneumocystis pneumonia, but larger cohort study is required to prove its usefulness for the diagnosis of pneumocystis infection.[70]

Diagnosis of Pulmonary Mycoses

With the increase of opportunistic fungal respiratory tract infections in tertiary care centers, especially with the increase of susceptible population, the real challenge is to suspect and diagnose and treat these infections early. Otherwise, these infections are associated with very high attributable mortality. Many centers recently reported unusually high incidence of opportunistic mycoses, including *Aspergillus spp*., *Fusarium spp*., *Scedosporium spp*. and *Zygomycetes*.[5] The time period between the first evidence of fungal infections and appearance of signs and symptoms represent a window of opportunity for early treatment. However, the present status of early diagnosis of these opportunistic mycoses is dismal. The European Organization for Research and Treatment of Cancer-Mycosis Study Group (EORTC-MSG) have developed a diagnostic protocol for invasive fungal infections in immunocompromised patients as proven, probable and possible infection depending on host, clinical and microbiological criteria.[74] The diagnosis of fungal infection depends on the combination of all three, instead of one criterion in isolation, though predictive value of the same may be high. Imaging helps to increase the suspicion of fungal disease. Therefore, the mycological tools should be used in conjunction with modern imaging techniques.[5]

Among mycological techniques, conventional procedures (direct microscopy, histopathology and culture) are not sensitive enough and do not help in early diagnosis. Maximum attention has been drawn to find suitable serological or molecular diagnostic technique. Polymerase Chain Reaction (PCR) for the detection of fungal nucleic acid in specimens, though holds promise, is awaiting further standardization and validation. Therefore, the relative merits of diagnostic tests for the detection of Galactomannan (GM) and beta-D-Glucan (BDG) are being evaluated. In recent year, a lot of experience has been gained with the Platelia *Aspergillus* seroassay (Bio-Rad Laboratories). This sandwich Enzyme Immunoassay (EIA) detects galactofuranose-containing molecules (including GM), cell wall components released by *Aspergillus* species during hyphal growth. Few other fungal organisms like *Penicillium* spp. share cross-reacting epitopes with *Aspergillus* species, but fortunately, these pathogens are rare in patients at risk for fungal respiratory tract infections.

The Platelia EIA is widely used as a screening tool for the early detection of invasive aspergillosis in neutropenic patients, though sensitivity results varied in different studies.[5] A single positive assay serves as a microbiological criterion to define probable invasive aspergillosis in patients with appropriate radiographic abnormalities. Platelia EIA has been used to detect *Aspergillus* antigen not only in serum, but also in BAL and pleural fluid. Data from one major center demonstrated excellent sensitivity of the Platelia EIA when used on BAL and pleural fluid.[75] It awaits: corroboration from other centers, treating similar patients. Of note, the use of Plasma-Lyte for performing BAL and the concomitant use of semisynthetic beta-lactam antibiotics, such as piperacillin/tazobactam may result in false positive test result.

Glucans are (1–3)-beta-D-linked polymers of glucose, which are part of the outer cell wall of most pathogenic fungi (except *Zygomycetes*, *Cryptococcus* species). D-Glucan can be detected by several commercial assays (Fungitell, Association of Cape Cod; Fungi-Tec G, Seikagaku Kogyo Corporation, Japan; Wako-WB003, Wako Pure Chemical Industries, Osaka, Japan). The negative predictive value of glucan detection test by twice weekly sampling is 100% and the sensitivity is 100%, if one positive assay is considered as a positive result, though overall experience with this assay remain limited.[76] The test requires endotoxin-free and glucan-free glassware. A number of factors, including the use of albumin or immunoglobulins, exposure to glucan-containing gauze and hemodialysis, may lead to false-positive readings in glucan detection test. The assay also cross-reacts with some antimicrobial preparations and can provide false positive result in patients with gram-positive bacteremia or *Pseudomonas aeruginosa* infections. Unfortunately, none of these serological assays helps in the diagnosis of other life-threatening fungal disease, invasive zygomycosis.[5,20,77,78]

Chest radiography is not a sensitive procedure for diagnosing pulmonary mold infections at an early stage. Chest CT scan helps to pick up the lesions. Classically, these infections present as macronodular lesions or infiltrates. In neutropenic patients approximately 80% of these nodular lesions will be surrounded by areas of lower attenuation or "halo sign" that represent areas of hemorrhagic inflammation.[5] The lesions eventually may cavitate during the course of therapy and following neutrophil recovery, creating what is commonly referred to as an "air crescent sign." However, these characteristics are neither highly sensitive nor fungal specific; other infections that elicit such inflammatory responses, including bacteria and viruses, can present with halo signs.[5,7]

In the absence of specific clinical symptoms and signs or radiological evidence, the big question is "Can we minimize the number of patients on empiric therapy in the high risk patients groups?" It is well known that the systemic antifungal therapy is toxic, expensive and has many drug interactions. Emphasis should be on preemptive therapy instead of empiric therapy (Table 54.5). Though contradictory suggestions are available, at least in neutropenic patients with persistent or recrudescent fever with no other clinical or radiological evidence of fungal disease, possibly the clinicians may withhold antifungal therapy when GM and glucan tests are negative, as the serological tests have excellent negative predictive value. Conversely, in a patient population in which a positive serological test correlates with a high positive predictive value, positivity should trigger a diagnostic work up, potentially leading to early therapy.[5] However, a highly suggestive CT scan and consecutive negative serological marker should trigger an aggressive diagnostic exploration (lung biopsy and imaging guided aspiration) for invasive zygomycosis, especially in countries like India where zygomycosis rate is very high.[5,52,79]

The diagnosis of pulmonary infections due to dimorphic fungi largely depends on clinical suspicion,

TABLE 54.5: Paradigms for antifungal intervention

Intervention	*Setting*
1. Primary prophylaxis	Prevention use in patients at high risk. General principle – consider prophylaxis when fungal infection rate ≥10% (prophylaxis is not substitute to hospital care practice)
2. Empirical therapy	Preventive use in patients with prolonged (≥10 days) neutropenia (ANC ≤ 500/μL) with persistent or new fever despite adequate broad-spectrum antibacterial therapy (adequate period varies on experience of particular center)
3. Preemptive therapy	Preemptive use in patients at high risk (≥10%) of invasive fungal infections who have imaging findings (Chest CT) and/or laboratory test results (positive for antigen or fungal specific markers) or specific score results consistent with invasive fungal infection by no conclusive evidence
4. Treatment–proven invasive fungal infections	Use in patients with direct microscopy or histopathological demonstration of fungal elements and/or microscopic documentation of a fungal organism in sterile body fluid or tissue
5. Secondary prophylaxis	Continuous use in patients who had a complete or partial response to treatment of an invasive fungal infection and need to undergo further intensive anticancer treatment or immunosuppression (till reversal of immunosuppression)

direct examination of respiratory specimens, histopathological examination of paraffin-embedded tissue and culture of appropriate samples. Careful examination of fungal structure on direct microscopy helps in identification of fungus as each dimorphic fungus has distinctive morphology in tissue. In an immunocompetent host serology for antibody detection helps in the diagnosis of considerable number of cases. Conversely in immunocompromised hosts antigen detection would be preferable alternative. However, only in histoplasmosis detection of a carbohydrate antigen in serum and urine is found to be useful for diagnosis and therapeutic monitoring.[80]

Therapy of Pulmonary Mycoses

The antifungal interventions may be used in the different paradigms (Table 54.5). The spectrum of activity of antifungal agents is provided in Table 54.6. (Also see Chapter 15 on antifungal drugs).

Presently, voriconazole is considered the drug of choice for the first line therapy of invasive aspergillosis. However, particular clinical conditions favor the use of a nonazole-based primary treatment, including prior exposure to mold-active azoles, the concomitant use of prohibited medication (e.g. sirolimus), the risk of severe drug interaction, moderate to severe renal impairment or the presence of mixed fungal infections (e.g. *Zygomycetes*).[5] Multi-azole-resistant *A. fumigatus* is also described.[81] Liposomal amphotericin B is considered alternative drug of choice for the first-line therapy of invasive aspergillosis. Data regarding the use of echinocandins in the primary therapy of invasive aspergillosis is scarce. Overall, up to 50% of the patients who fail first line therapy can be salvaged with second-line use of caspofungin, posaconazole or a lipid formulation of amphotericin B.[5,82,83]

Voriconazole and amphotericin B (preferably a lipid-based formulation) are also considered drug of choice for the treatment of *Fusarium* and *Scedosporium* infections. Posaconazole may be used as salvage therapy.[84-86] For zygomycosis high dose of lipid-based formulations of amphotericin B (up to 10 mg/kg) remain the drug of choice for the first-line therapy, whereas posaconazole may be used in salvage or maintenance treatment. Surgical excision of infected lesions and reversal of underlying predisposing factors are also important in the management of pulmonary zygomycosis and should complement antifungal therapy.[52,87]

Treatment of pulmonary mycoses due to dimorphic fungi depends on the competency of the hosts and disease pattern. Self-limiting disease among immunocompetent hosts are managed with supportive care. Acute pulmonary histoplasmosis or blastomycosis is treated with itraconazole. However, profoundly immunocompromised hosts or those with severe disease are treated with amphotericin B, preferably lipid formulations. itraconazole or amphotericin B has been proven to effective also against penicilliosis.[88-91] In pulmonary cryptococcosis, if the patient is HIV infected, an initial course of amphotericin B with or without

TABLE 54.6: Spectrum of activity of antifungal agents

Organism	*AMB*	*FCZ*	*ITZ*	*PCZ*	*VCZ*	*CAS*	*ANID*	*MICA*	*5FC*
Candida albicans	*S*	*S*	*S*	*S*	*S*	*S*	*S*	*S*	*S*
C. glabrata	S-I-R	SDD-R	S-I	S-I	S-I	S	S	S	S
C. parapsilosis	S	S	S	S	S	S-I	S-I	S-I	S
C. krusei	S-I-R	R	I-R	S-I-R	S-I-R	S	S	S	I-R
Cryptococcus neoformans	S	S	S	S	S	R	R	R	S

Hyalohyphomycetes	I-R	R	S-I-R	S-I-R	S-I-R	R	R	R	R
Phaeohyphomycetes	S-I	R	S	S	S	I-R	I-R	I-R	S-R
Dimorphic fungi	S	S-R	S	S	S	-	-	-	S-R

AMB = amphotericin B, FCZ = fluconazole, ITZ = itraconazole, PCZ = posaconazole, VIZ = voriconazole, CAS = caspofungin, ANID = anidulafungin, MICA = micafungin, 5FC = 5 fluorocystosine flucytosine, followed by maintenance therapy with fluconazole is recommended. Itraconazole may be used as alternative therapy in patients with the mild disease of pulmonary cryptococcosis.[92,93]

In allergic fungal pulmonary diseases like ABPA, corticosteroids are recommended. Early aggressive disease may slow down the irreversible fibrotic phase. Itraconazole may be added in resistant cases. In allergic fungal sinusitis, systemic steroids are found better than local steroids. Itraconazole may be effective in combination with corticosteroids. For fungal ball in sinuses and aspergilloma in lung, current therapeutic approaches include conservative management and surgical resection.[94-96]

Pulmonary Mycetoma

Alladi Mohan, B Vijayalakshmi Devi, Abha Chandra

INTRODUCTION

The genus aspergillus includes saprophytic, ubiquitous, soil dwelling organisms that are found in organic debris, dust, compost, food items, and damp areas such as basements.[1] While there are approximately 200 species of aspergillus, only a few are known to cause disease in human beings. Among these, *Aspergillus fumigatus* is responsible for nearly 90% of all human infections. Several other important species that cause human disease include *Aspergillus flavus* and *Aspergillus niger*. Rarely, species, such as, *Aspergillus terreus*, *Aspergillus clavatus*, *Aspergillus niveus*, *Aspergillus nidulans,* among others have been implicated in the causation of human disease.[2-5]

PATHOGENESIS

Aspergillus grows at 15ºC to 53ºC and can thrive in the human respiratory tract. It is a spore-forming fungus with septate dichotomous branching hyphae. These hyphae branch at an acute angle and contain conidiophores, which harbor hundreds of conidia or spores. The spores are easily dispersed by air currents or physical contact.[1-3,6] Aspergillus infection is usually acquired from an inanimate reservoir, by the inhalation of airborne spores and these spores are common inhabitants of the airway. Even though humans may inhale hundreds of these spores daily, only some develop disease from Aspergillus manifesting as a variety of clinical syndromes.

Pulmonary mycetoma (aspergilloma), a saprophytic manifestation of aspergillosis, usually develops in a preexisting cavity in the lung and is the most common and best recognized form of pulmonary involvement due to aspergillus. Impairment or absence of normal mucociliary clearance mechanisms in a cavity may facilitate the adherence and germination of fungal conidia resulting in the formation of a pulmonary mycetoma. Some workers have also postulated that inflammatory reaction in the cavity and the ensuing secretion of toxins, enzymes and other mediators of inflammation may facilitate creation or advancement of a cavity.[7]

Pulmonary mycetomas have been most commonly reported in the cavities of pulmonary tuberculosis. They have also been described in other lung diseases associated with cavity formation (Table 55.1).[2-5,8-14] There have been case reports from India of pulmonary aspergilloma occurring in a hydatid cavity[15] and in patients with cavitary sarcoidosis.[16]

PATHOLOGY

Pulmonary mycetomas grow in the areas of devitalized lung such as a cavity, damaged bronchial tree or a pulmonary cyst. Aspergillomas have been described in cavities in the lung parenchyma, bronchi and pleura. They consist of the masses of living and dead fungal mycelia, inflammatory cells, fibrin, mucus, other blood products and tissue debris, are solid and are fragmented only with force.[2-5] Tissue invasion by the fungus does not occur in pulmonary mycetoma. Inadequate drainage is thought to facilitate the growth of aspergillus on the walls of these cavities.[2]

Earlier, aspergillomas have been classified as simple and complex aspergillomas.[17] Simple aspergillomas develop in isolated thin walled cysts of bronchial origin,

there is little or no abnormality in the surrounding lung and the cyst wall itself is usually lined by ciliated epithelium. Complex aspergillomas develop in cavities with gross disease in the surrounding lung tissue.[17] Recently, aspergillomas have been classified as simple and chronic cavitary pulmonary aspergillosis.[18] Simple aspergillomas are encased by thin walled cysts with little surrounding parenchyma disease. Chronic cavitary pulmonary aspergillosis is associated with thick walls, multiple cavities (that may or may not contain fungal balls), and surrounding parenchymal changes (Table 55.2).[18]

Natural History

In the majority of cases, the aspergilloma remains stable, but in up to 10% of cases the lesion may decrease in size or resolve spontaneously without treatment.[2,3,19] However, rarely, progressive enlargement of a single thin walled cavity may occur slowly over months or rapidly within weeks. These patients have minor or moderate degrees of immune dysfunction, such as diabetes mellitus or corticosteroid use. This entity has been called chronic necrotizing pulmonary aspergillosis (subacute invasive aspergillosis).[18] Although aspergillomas are often thought of as benign saprophytic colonizations of the lung with *aspergillus,* invasive pulmonary aspergillosis may develop from an aspergilloma and may be often fatal.[20]

CLINICAL PRESENTATION

Patients with aspergilloma may remain asymptomatic for several years and the pulmonary mycetoma may be evident as an incidental finding on radiographic studies carried out for some other purpose.[2-5] Symptomatic patients with simple pulmonary aspergilloma commonly present with hemoptysis. The source of hemoptysis is usually bronchial artery;[2,3] rarely anastomotic plexus between pulmonary and bronchial arteries[21] has been implicated as the cause. The various causes of hemoptysis in patients with pulmonary

Table 55.2: Comparison of characteristics of simple aspergilloma and chronic cavitary pulmonary aspergillosis

Variable	*Simple pulmonary aspergilloma*	*Chronic cavitary pulmonary aspergillosis (complex aspergilloma)*
Clinical symptoms	None or minimal	Significant pulmonary and systemic symptoms
Host immunity	Not immunocompromised	Not immunocompromised; or, the immunocompromised state has remitted or is trivial
Radiographic findings	Single pulmonary cavity containing a fungal ball	One or more pulmonary cavities, which may or may not contain a fungal ball
Serological/microbiological evidence of infection with *Aspergillus species*	Yes	Yes
Progression of disease	No radiological progression over at least three months of observation	Radiological progression (new cavities, increasing pericavity infiltrates or increasing fibrosis) is evident over at least three months of observation. Hyphae are found in the cavity, but the wall of the cavity is composed of chronic inflammatory cells and fibrosis, but not tissue invasion. In some patients, a strong pleural/pulmonary fibrosis may result in chronic fibrosing pulmonary aspergillosis

Table 55.3B: Causes of hemoptysis in patients with aspergilloma

Mechanical friction of the blood vessels in the cavity wall by the moving fungal ball
Local invasion of blood vessels lining the cavity
Endotoxins released by the fungus with hemolytic properties
Release of trypsin like proteolytic enzymes
Type III (antigen-antibody) hypersensitivity reaction resulting in injury to cavity wall and hemorrhage

aspergilloma are listed in Table 55.3. Hemoptysis has been described in 69 to 91% of patients in some of the recently published studies.[11,22,23] In the series published from India,[21,24,25] this figure ranged from 65 to 93% (Tables 55.4A and B). The severity of hemoptysis may range from mild to massive and life threatening. In the series published from India, massive hemoptysis requiring bronchial artery embolization/surgery was observed in 7 to 18%[21,24,25] of patients.

Other symptoms include chronic cough and breathlessness (Tables 55.4A and B). These symptoms may probably be due to the underlying lung disease. Expectoration of blackish brown sputum (melanoptysis) has also been documented in patients with pulmonary aspergilloma.[26,27] Occasionally fever and weight loss may be present and usually signifies secondary bacterial infection.

Rare Manifestations

Coexistence of active pulmonary tuberculosis disease is uncommon in patients with pulmonary aspergilloma, but has rarely been documented.[28] The occurrence of pulmonary aspergilloma in patients with allergic bronchopulmonary aspergillosis is also uncommon.[29,30] Clinical presentation with pneumothorax has also been reported.[31]

Pulmonary Mycetoma in Special Situations

Human Immunodeficiency Virus (HIV) Seropositive Individuals

Apart from occasional case reports of aspergilloma in HIV infected individuals,[32-35] there have been few publications on pulmonary mycetoma in HIV seropositive individuals. In the series reported by Addrizzo-Harris et al.[12] 10 of the 25 patients with pulmonary aspergilloma were HIV serpositive. Seven of the ten HIV seropositive patients had a history of pulmonary tuberculosis and three of them had a history of *Pneumocystis jiroveci* pneumonia (PCP). Severe hemoptysis (>150 mL/day) occurred in 5 of 15 (33%) in the HIV negative group compared with 1 of 10 (10%) of the HIV infected group. Compared with HIV seronegative individuals, disease progression occurred more frequently among the HIV seropositive individuals with a CD4+ T-lymphocyte count <100/mm^3 (4/8, 50% vs 1/13, 8%; p=0.05). Mortality was also higher among HIV infected individuals (4/8, 50% vs 1/13, 8%; p = 0.05). More data are required to further understand these issues.

Lung Transplant Recipients

Aspergillomas have been reported in two single lung transplant recipients both of whom presented with hemoptysis in the series reported by Westney et al.[36]

Neutropenic Patients

While invasive pulmonary aspergillosis has frequently been described in patients with neutropenia, the occurrence of pulmonary mycetoma has also been occasionally described. Kibbler et al.[37] reported four such cases and reviewed the literature regarding 34 similar cases. Acute myeloid leukemia was the most common underlying diagnosis in these patients (17 of the 38 patients, 45%). Hemoptysis occurred in nearly 50% of the patients and the mortality was approximately 25%. As these pulmonary mycetomas did not develop in preexisting lung cavities, but developed in necrotic lung tissue due to fungal invasion, Kibbler et al.[36] suggested the term "mycotic lung sequestration" for this condition. Considering the potential for the progression of disease, immunosuppressed patients who have aspergilloma should be monitored closely for this complication.

DIAGNOSIS

The diagnosis of pulmonary mycetoma is usually established on the basis of clinical presentation and radiographic features, combined with serological or microbiologic evidence of infection with aspergillus species.[6,38] In patients with a past history of pulmonary tuberculosis presenting with hemoptysis, the possible differential diagnosis includes relapse, reactivation/reinfection tuberculosis, aspergilloma, scar carcinoma, among others. The diagnostic work-up should include testing for ruling out these causes.

Chest Radiograph

The chest radiograph is useful in demonstrating the presence of a pulmonary mycetoma. In a chest

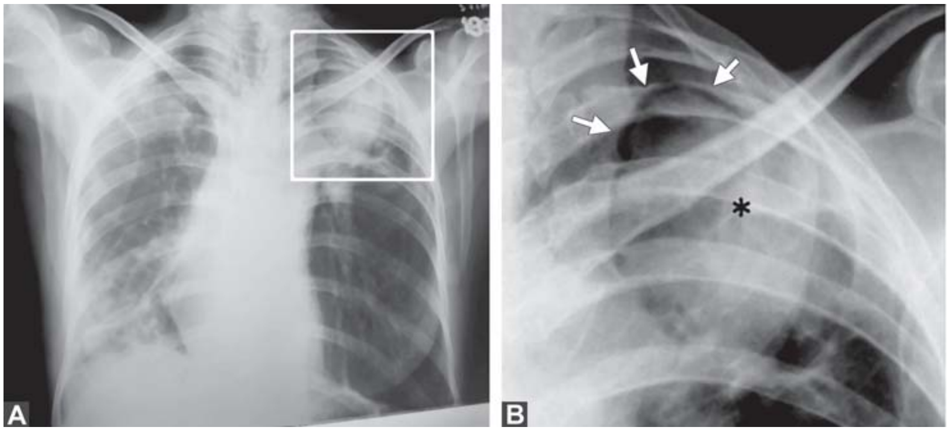
radiograph, aspergilloma appears as a mobile, spherical intracavitary mass that is separated from the cavity by an air space that appears as an "air-crescent" in the periphery (Figs 55.1A and B).[2-5,39] As these lesions usually develop in a preexisting pulmonary tuberculosis cavity, the lesions are frequently found in the upper lobes.[40] After moving the patient from supine to prone position, a change in the position of the fungus ball can be demonstrated.[2-5,39] If the lesion is peripherally located, pleural fibrosis is frequently evident. The chest radiograph may also reveal the sequelae of the pre-existing lung disease.

TABLE 55.4B: Surgical treatment, complications and mortality documented in studies from India

Variable	*Akbari et al*[24]	*Pratap et al*[25]
Place of study	Thiruvananthapuram, Kerala	New Delhi
Year of publication	2005	2007
No. of patients	60	72
Treatment	Lobectomy (n = 55), pneumonectomy (n = 02), segmental resection (n = 02), and cavernoplasty (n = 02). One patient underwent bilateral lobectomy at 14 months interval	Pneumonectomy (n = 21); lobectomy (n = 51). In 10 of the right upper lobe lesions, bilobectomies were done, by removing both the right upper and middle lobes, due to presence of adhesions
Morbidity*	12/46 complex aspergilloma patients (26%)	22/64 complex aspergilloma patients (34%)
Major complications*	Air-leak (>10 days) (n = 4), bleeding (n = 2), empyema (n = 4), respiratory problems (n = 1), wound dehiscence (n = 1)	Air-leak (>10 days) (n = 5), massive hemorrhage (n = 5), persistent pleural space (n = 3)
Mortality in complex pulmonary aspergilloma	02/46 (4%)	02/64 (3%)
Over all mortality (%)	02/60 (3%)	02/72 (3%)

All values corrected to the nearest round figure

* Morbidity and mortality were observed only in patients with complex aspergilloma. Surgery was uneventful in patients with simple aspergilloma



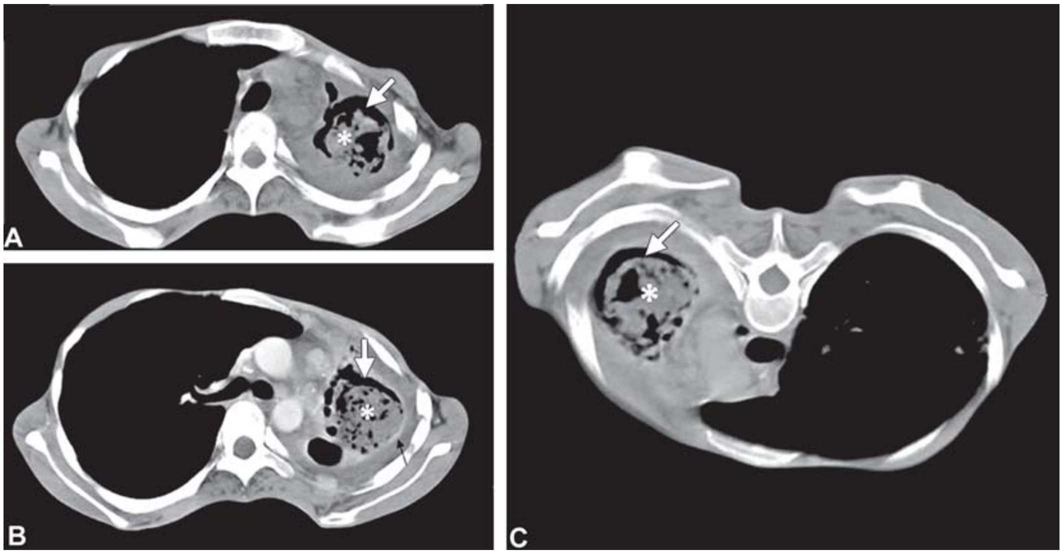
Figs 55.1A and B: Chest radiograph (posteroanterior view) (A) of a patient with past history of pulmonary tuberculosis who presented with hemoptysis showing parenchymal infiltrates in both upper zones, fibrotic changes in right lower zone. In the left upper zone, a spherical intracavitary fungal ball that is separated from the cavity by an air-space that appears as an "air-crescent" in the periphery (square) can also be seen. Close-up view of the same (B) showing a intracavitary fungal ball (asterisk) that is separated from the cavity by an air-space that appears as an "air crescent" in the periphery (arrows)

Computed Tomography

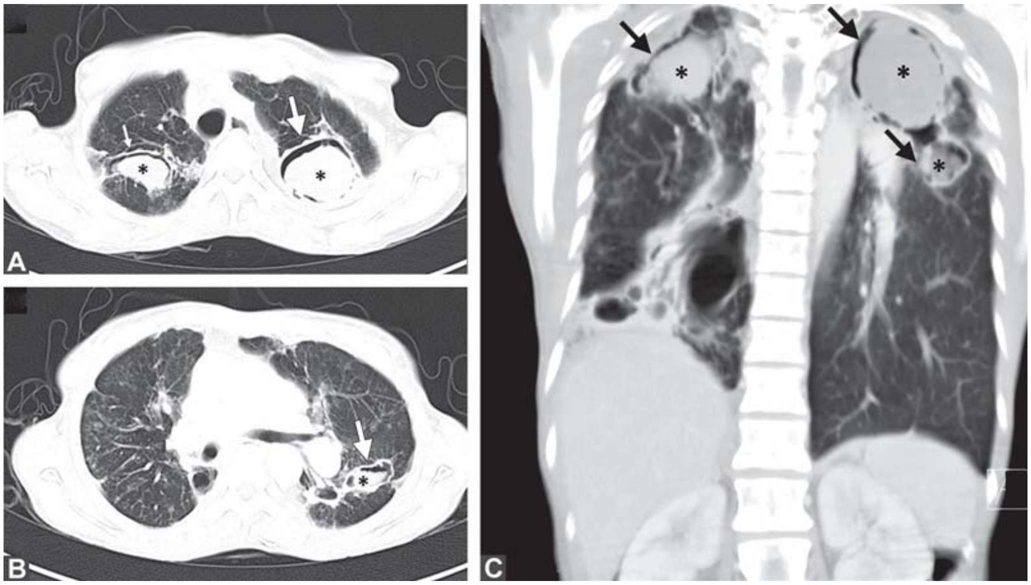
Computed tomography (CT) is increasingly being used for the evaluation of patients with pulmonary mycetoma. The CT offers the advantages of facilitating the better delineation of fungal ball and air crescent and documenting the change in the position of the fungal ball (Figs 55.2 and 55.3). The CT also facilitates the detection of fungal balls that may not be discernible on the chest radiograph. Coexistent lung disease, sequelae of previous lung disease can also be appreciated better on CT.[2-5]

Differential Diagnosis

Radiologically, aspergillomas must be differentiated from hematoma, neoplasm, abscess, hydatid cyst and Wegener's granulomatosis. However, aspergilloma may coexist with any of these conditions.[41-43] In one study[43] the mural nodules within cavitating lung cancer were more enhanced and showed a nondependent location more frequently than those of intracavitary aspergillomas. The cavitary walls were significantly thicker in cavitating lung cancer (mean thickness 5.8 mm)



Figs 55.2: Computed tomography of the chest (plain study, mediastinal window) and (A) contrast enhanced study (lung-window) (B) showing an intracavitary fungal ball (asterisk) that is separated from the cavity by an air-space that appears as an “air-crescent” in the periphery (white arrow); thickened pleura is also evident (black arrow). CECT chest obtained after moving the patient from supine to prone position (C) shows a change in the position of the fungus ball (asterisk) and the air-crescent (arrow)



Figs 55.3A to C: CECT of the chest (A) of the same patient shown in Figure 55.1A showing complex pulmonary aspergillomas (asterisk) in both upper lobes and another aspergilloma in the left upper lobe; (B) air-crescent sign (arrow) is also evident. Coronal reconstruction (C) reveals the aspergillomas (asterisks), air-crescent sign (arrow) and fibrocavitary disease. The CT was helpful in revealing several other details that were not discernible in the chest radiograph (Figs 55.1A and B)

than those in intracavitary aspergillomas (mean thickness 2.6 mm). Adjacent bronchiectasis and volume decrease of the involved lobe were observed more frequently in intracavitary aspergillomas than in cavitating lung cancers.

Serological and Microbiological Methods

Sputum, bronchoalveolar lavage (BAL) fluid culture may reveal the presence of aspergillus species in 50% of the patients with pulmonary aspergilloma.[6,38] Serum precipitins [immunoglobulin G (IgG) antibodies] against *Aspergillus fumigatus* are usually positive in almost all the cases; false-negative reports have been described in patients receiving corticosteroid treatment and in mycetomas caused by species other than *A. fumigatus*.[6,38]

Histopathology

Histopathological evidence of aspergilloma (Figs 55.4A to C) may be established in surgically excised specimens by demonstrating acute-angle branching, septate, non-pigmented hyphae measuring 2 to 4 µ in width that are best demonstrated with best detected by Gömöri methenamine silver and periodic acid–Schiff stains.[6,38] However, *Aspergillus* hyphae are histopathologically difficult to distinguish from those of *Fusarium* species, *Pseudallescheria boydii,* agents of phaeohyphomycosis, among others.

Molecular Methods

Polymerase Chain Reaction (PCR) has been used for the diagnosis of pulmonary aspergilloma. Polymerase Chain Reaction amplification of Asp fI (18 kDa) and alkaline protease (33 kDa) antigens derived from *A. fumigatus* and implicated as possible virulence factors in the pathogenesis of *Aspergillus* induced diseases has been found to be useful for the diagnosis of pulmonary aspergilloma.[44] In another study,[45] TacMAN-MGB probes, which covered the loci Gly 54, Leu 98, Glyw 138 and Met 220 of the enzyme CYP 51A coded by the gene cyp 51A, as well as the 34-bp tandem repeated sequence in the promoter region (-288 and -322 from the start codon) of this gene, was useful in detecting itraconazole resistant strains of *A. fumigatus*. These protocols need to be evaluated in the field setting.

TREATMENT

The optimal treatment strategy for patients with pulmonary mycetoma is unknown and there is no consensus regarding the choice or timing of therapy. Treatment aims at preventing life threatening hemoptysis.

Surgery

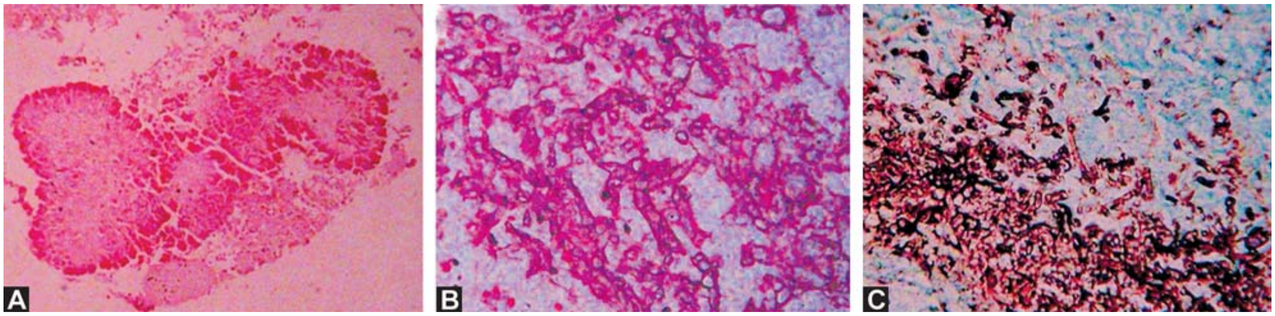
Surgical removal of aspergilloma is the definitive treatment. However, in view of the morbidity and mortality associated with the procedure, it has to be used judiciously. As per the recent Infectious Disease Society of America (IDSA) guidelines[38] surgery is indicated as the definitive treatment in patients with the episodes of life threatening hemoptysis, and those who are at risk for such a complication, like patients with underlying sarcoidosis, immunocompromised patients, and those with increasing *Aspergillus* specific IgG titres.

Morbidity

Commonly observed postoperative complications include hemorrhage, incomplete lung reexpansion, prolonged air leak, empyema and respiratory failure, wound infection, respiratory insufficiency and chylothorax.[11,46-51] Various surgical procedures used in the treatment of pulmonary aspergilloma in two studies from India[24,25] and associated morbidity are shown in Table 55.4B.

Mortality

Surgery for pulmonary aspergilloma was associated with a high mortality rate, ranging from 7 to 23% in earlier



Figs 55.4A to C: Photomicrograph of a surgically excised specimen showing an aspergilloma (A) (Hematoxylin and eosin × 100). Under high power view (B) acute-angle branching, septate, non-pigmented hyphae measuring 2 to 4 µ can be seen (Hematoxylin and eosin × 400). The fungal hyphae are better appreciated on Gömöri methenamine silver staining (× 400) (C)

(*Courtesy:* Dr KV Sreedhar Babu, Department of Pathology, Sri Venkateswara Institute of Medical Sciences, Tirupati) studies.[11,46-51] More recent data from nine published studies[52-59] (n=456) reveal a cumulative mortality rate of 2.3%.[4] Surgical mortality has been reported to be less than 1% for simple aspergilloma.[2-5] In two large Indian studies published recently, the overall mortality rate was 3% (see Table 55.4B).[24,25] All deaths had occurred in patients with complex aspergilloma and in this group of patients, the mortality ranged from 3 to 4% (see Table 55.4B).

Since aspergilloma do not result in life threatening hemoptysis in a majority of the patients, the morbidity and the expense involved in the treatment must be weighed against the clinical benefits. Asymptomatic patients with pulmonary mycetoma should be carefully followed-up for their life time as they have a potential for developing hemoptysis.

Bronchial Artery Embolization

Patients with life threatening hemoptysis who require surgery would need to have adequate pulmonary function to undergo the operation. However, several patients are sick and may not be fit to undergo major surgery. Bronchial artery embolization may be useful as a temporary life saving procedure in patients with life threatening hemoptysis. Unlike several other conditions where bronchial artery embolization produces more favorable outcome, the results have not been as promising for patients with aspergilloma.[60] In the study reported by Kim et al.[61] (n = 118), the only significant factor associated with rebleeding one year after bronchial artery embolization was the presence of an aspergilloma (n = 32). Presently, bronchial artery embolization is not considered to be a replacement for surgery, but, is recommend by the IDSA guidelines[38] as a short-term therapy to stabilize patients for more definitive treatment, including surgery.

Medical Treatment

The role of intravenously administered amphotericin B failed to show a benefit in patients with aspergilloma.[62] Inhaled, intracavitary and endobronchial instillation of antifungal agents has been tried with limited success for the treatment for aspergilloma.[22,63,64] Intracavitary administration of transthoracic, percutaneous amphotericin B into the under CT guidance has been found to be useful in patients with massive hemoptysis, with the resolution of hemoptysis occurring within few days. While the results have been promising in some of the studies,[62,65-67] simliar success was not documented in others.[68,69]

Itraconazole has a high tissue penetration and significant itraconazole levels have been demonstrated within the cavity containing aspergilloma.[70] Oral itraconazole has been used with promising results in patients with aspergilloma with symptomatic and radiographic improvement being evident in half to two-thirds of patients; and a complete response in the occasional patient.[66-68] However, itraconazole works slowly and may not be useful in patients presenting with life-threatening hemoptysis.

According to the IDSA guidelines,[38] for patients with pulmonary aspergilloma, voriconazole (6 mg/kg IV every 12 hour for one day, followed by 4 mg/kg IV every 12 hour; oral dosage is 200 mg every 12 hour), or itraconazole (dosage for tablets is 600 mg/day for three days, followed by 400 mg/day; parenteral dosage is 200 mg every 12 hour IV for 2 days, followed by 200 mg daily thereafter are advocated as the alternatives to surgery, which is advocated as the primary therapeutic strategy. For chronic cavitary pulmonary aspergilloma, these guidelines[38] indicate voriconazole and itraconazole as the primary therapy. Potential utility of therapy with interferon-gamma in pulmonary aspergilloma has occasionally been documented[18,38] and merits further study.

PROGNOSTIC FACTORS

Factors associated with a poor prognosis in patients with aspergilloma include severe underlying lung disease, increasing size or number of lesions on imaging, presence of immunosuppression (including corticosteroid treatment), increasing *Aspergillus*-specific IgG titers, recurrent large volume hemoptysis, and underlying sarcoidosis or HIV infection.[6]

OVERALL MORTALITY

Mortality in patients who have pulmonary aspergillomas has been reported to be 5 to 6% per year.[4] In a retrospective study[22] of 85 cases over 24 years, overall mortality over 10 years was 56%, with 10 deaths directly attributable to aspergillomas. The age of the patients and underlying comorbid lung disease also seem to have a bearing on the mortality.

CONCLUSION

Pulmonary mycetomas most often develop in old tuberculosis cavities. Majority of patients with pulmonary mycetomas remain asymptomatic and the lesions may be picked up on a routine chest radiograph carried out for some other purpose. Pulmonary aspergillomas are often noticed by clinicians when patients present with hemoptysis. In patients who present with life threatening hemoptysis and are fit, surgery is the preferred treatment of choice. Bronchial artery embolization may be used as a temporary measure to control bleeding. Therapy with voriconazole and itraconazole appear to be useful. Asymptomatic patients should be carefully followed-up periodically for their lifetime as they have potential for developing life threatening hemoptysis.

Nosocomial Pneumonia

Vishwanath Gella, SK Jindal

INTRODUCTION

Nosocomial pneumonia has been defined as an infection of the lung parenchyma that was neither present nor incubating at the time of hospital admission. It includes Hospital-Acquired Pneumonia (HAP), Ventilator-Associated Pneumonia (VAP) and Health Care-Associated Pneumonia (HCAP), which are significant problems world wide. These pneumonias are responsible for an increased mortality, hospital stay and health care costs for patients.

Definitions According to ATS/IDSA Guidelines[1]

Hospital-acquired pneumonia is defined as pneumonia occurring 48 hours after admission and does not appear to be incubating at the time of admission. Similarly, VAP is defined as pneumonia occurring 48–72 hours after endotracheal intubation. Health care-associated pneumonia is a relatively new term for pneumonia occurring in patients in the nonhospital settings, but who have got extensive health care contact. HCAP excludes HAP, VAP and Community-Acquired Pneumonia (CAP), and is associated with the following risk factors:

a. Hospitalization for more than two days in the preceding 90 days
b. Residence in a nursing home or in an extended care facility
c. Home infusion therapy
d. Patients receiving chronic dialysis or home wound care

PATHOGENESIS

The main mechanism involved in the pathogenesis of nosocomial pneumonia is through the colonization of oropharynx and Gastrointestinal Tract (GIT) with pathogenic microorganism leading to microaspiration of these contents. Colonization can occur in almost 75% of hospitalized patients within 48 hours, predominantly due to a breach of normal mucosal integrity (from numerous invasive devices—nasogastric, endotracheal tube and urinary catheter), contact through health care personnel, and colonization of endotracheal tube biofilm. Factors that lead to an increase in the gastric pH like an acute illness, or drugs can disrupt the sterility of the stomach and upper GIT and lead to colonization. There are multiple reasons for aspiration such as the altered level of consciousness, depressed gag reflex, impaired swallowing and altered gastrointestinal motility. Though endotracheal tube may prevent macroaspiration, it does not prevent microaspiration around the cuff of the tube. Sometimes, the microorganisms inhabiting the biofilm of the endotracheal tube can get dislodged and reach the lower respiratory tract. Further, it depends on the number and virulence of microorganisms, and the host defenses whether VAP develops or not. Rarely, hematogenous spread from a focus of sepsis can lead to VAP.

DIAGNOSIS

Diagnosis of HAP/HCAP is predominantly based on clinical, radiological and sputum evaluation. The data on HAP/HCAP is mainly extrapolated from studies from VAP. Ventilator-associated pneumonia should be suspected in all intubated patients who develop new onset fever, respiratory symptoms, and/or new chest infiltrates; in patients on ventilator with increased respiratory rate, increased minute volume, decreased tidal volume and increasing oxygen requirement. There are two different strategies to diagnose VAP. Clinical approach and quantitative bacteriological approach.[1]

Clinical Approach

In this approach, diagnosis of VAP/HAP is based on the presence of new radiographic infiltrate and presence of two out of three following clinical criteria—fever, leukocytosis or leukopenia, purulent lower respiratory secretions.

The specificity of the clinical criteria is increased by the addition of microscopic examination and semi-quantitative cultures of tracheal aspirate. Microscopic examination of the tracheal aspirate for gram stain and white blood cells will guide empirical treatment and prevent inappropriate therapy. A negative tracheal aspirate for gram stain, inflammatory cells and nonquantitative cultures in the absence of recent change in antibiotic therapy (within 72 hours) has a strong negative predictive value (94%) for VAP, and in such cases other noninfectious causes of pulmonary infiltrates need to be ruled out.[2] Semiquantitative cultures are reported as light, moderate or heavy growth.

Semiquantitative tracheal aspirate cultures are highly sensitive, but have low specificity and cannot differentiate colonization from infection. However, combined with clinical criteria, their specificity increases. Clinical approach hinges on the fact that failure to initiate treatment in the cases of VAP as soon as the diagnosis is suspected, will lead to increased mortality. All the patients suspected to have VAP will receive broad spectrum antibiotics according to risk factors and local microbiological epidemiology after lower respiratory tract secretions are sent for culture, but the initiation of the antibiotics should not be delayed for obtaining cultures especially in hemodynamically unstable patients. Other mimics of pulmonary infection, such as atelectasis, Pulmonary Thromboembolism (PTE), hemorrhage and congestive heart failure, which can present with similar clinical manifestations, should be ruled out before considering the diagnosis of VAP/HAP. It may sometimes lead to excessive antibiotic treatment if other mimics are not excluded before labeling a patient as having VAP.

Clinical Pulmonary Infection Score (CPIS) has been devised to increase the specificity of clinical diagnosis, it incorporates clinical, radiological, physiological (Pao_2/Fio_2) and microbiological data into a single numerical result.[3] When the score of CPIS exceeded six, a good correlation was found with quantitative cultures of specimens obtained by bronchoscopic and non-bronchoscopic methods. A CPIS score of </= 6 at 72 hours has been used to stop antibiotics without adversely affecting mortality and Intensive Care Unit (ICU) stay, but needs to be studied in a larger population.[4] However, subsequent studies did not show good sensitivity and specificity of CPIS for the diagnosis of VAP.

Clinical response after 48–72 hours in combination with semiquantitive cultures are taken into consideration to decide the further course of action regarding antibiotics.

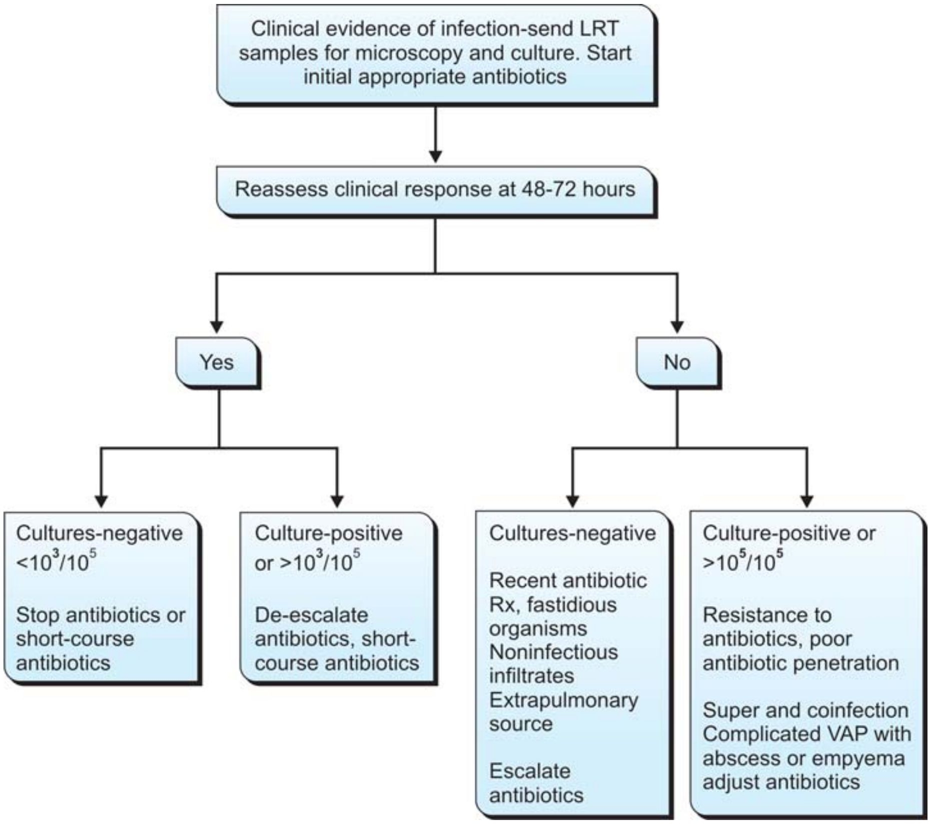
Quantitative Microbiological Approach

The Achilles heel of this approach lies in avoiding over treatment, thereby preventing resistance to antibiotics. Quantitative cultures on the other hand are more specific, but less sensitive and differentiate colonization from infection when a specific threshold is taken for diagnosis of VAP.

The growth of the bacteria in the respiratory samples above the threshold indicates infection, growth below the threshold indicates colonization. These samples can be collected bronchoscopically or blindly. The more distal the sampling from the lower respiratory tract, the more specific and less sensitive it is. So, the lower respiratory tract secretions obtained through Bronchoalveolar Lavage (BAL) and Protected-Specimen Brush (PSB) are highly specific. Mini-BAL and blind endotracheal aspirate (non-bronchoscopic) quantitative cultures have high sensitivity and low specificity, retaining the diagnostic accuracy. However, it has been shown that bronchoscopic sampling and quantitative culture techniques as compared to non-bronchoscopic and nonquantitative cultures, do not improve mortality, length of hospital stay, duration of mechanical ventilation, or length of ICU stay, but may lead to choice of narrower spectrum of antimicrobial therapy and early de-escalation of antibiotics.[5,6]

The threshold varies depending on the site from which sample has been taken. A threshold of 10^6, 10^4 to 10^5 and 10^3 cfu/ml has been taken as cut-off for blind endotracheal aspirate, BAL and PSB respectively. Patients are treated only if the quantitative cultures exceed the threshold. The main disadvantage of this approach is the failure to treat a patient with false-negative culture report, and lack of immediate availability of the culture report. To overcome this

Flow chart 56.1: An algorithmic approach to the diagnosis of VAP



Clinical evidence of infection-send LRT samples for microscopy and culture. Start initial appropriate antibiotics
Reassess clinical response at 48-72 hours
Yes
No
Cultures-negative $<10^3/10^5$
Stop antibiotics or short-course antibiotics
Culture-positive or $>10^3/10^5$
De-escalate antibiotics, short-course antibiotics
Cultures-negative
Recent antibiotic Rx, fastidious organisms
Noninfectious infiltrates
Extrapulmonary source
Escalate antibiotics
Culture-positive or $>10^5/10^5$
Resistance to antibiotics, poor antibiotic penetration
Super and coinfection
Complicated VAP with abscess or empyema
adjust antibiotics

problem, the clinician can take clues from the Giemsa or Gram-stain of the endotracheal aspirates to guide the initial appropriate therapy. False-negative cultures can occur in the cases of specific pathogen, recent start of antibiotics or cultures taken after starting antibiotics. Threshold for diagnosis may be lowered in such cases to increase the sensitivity.

A combined approach following algorithm is better in view of the short-comings of both the approaches (Flow chart 56.1).

RISK STRATIFICATION OF PATIENTS WITH VAP

Presently, there is no score to assess the severity of VAP at the time of diagnosis. APACHE II has not been shown as a good modality for risk stratifying these patients as shown in a matched cohort study.[7] Analogous to the TNM classification used in cancers, experts have come up with a relatively new concept of stratification (PIRO). This is based on predisposition (P), insult/infection (I), host response (R) and organ dysfunction (O). This concept was built upon a system of IRO during the 2001 International Sepsis Definitions Conference, which discussed the weaknesses of Systemic Inflammatory Response Syndrome (SIRS) and sepsis definitions.[8] By mixing the PIRO concept with VAP, a VAP-PIRO score was created.[9] On multivariate analysis, four variables were associated with mortality presence of comorbidities: Chronic Obstructive Pulmonary Disease (COPD); immunocompromised, heart failure, cirrhosis, or chronic renal failure (predisposition-P), bacteremia (infection/insult-I); systolic blood pressure below 90 mm Hg or need of vasopressors to maintain blood pressure (response-R); and Acute Respiratory Distress Syndrome (ARDS) (organ dysfunction-O). These results were converted into a four variable PIRO score with one point assigned to each variable, with the score ranging from 0 to 4. The mortality increased significantly as the score increased (Table 56.1).

TABLE 56.1: Categorization and mortality according to the VAP-PIRO score

Risk category	*Score*	*Mortality*
Mild risk	0–1points	9.8–17%
High-risk	2 points	52.9%
Very high-risk	3–4 points	76.5–93.3%

TREATMENT

Appropriate initial antibiotic therapy improves survival. Initial inappropriate therapy has been shown to increase the mortality in patients with severe sepsis and VAP. The most important factor for initial inappropriate therapy is the presence of Multidrug-Resistant (MDR) pathogens in culture reports obtained subsequently after admission; the mortality risk does not decrease even if antibiotics are changed subseq uently. So, the most important step in the treatment of VAP is to identify patients at risk of MDR pathogens and treat them appropriately from the beginning itself. Initial broad spectrum empirical therapy has been advocated for use in patients with risk factors, identified in the 2005 ATS/IDSA guidelines (Table 56.2).

TABLE 56.2: Risk factors for MDR pathogens

Infection occurring five days after hospitalization

High antibiotic resistance in the community/hospital

Presence of pulmonary comorbidities, immunosuppressive therapy or disease

Risk factors for HCAP leading to MDR pathogens

Antibiotic therapy in preceding 90 days

Hospitalization for more than two days in preceding 90 days

Residence in nursing home or extended care facility

Home infusion therapy, including antibiotics, recent chemotherapy

Attending hemodialysis clinic

The recent literature outlines the specific risk factors for specific pathogens (e.g. MRSA in hemodialysis patients) and also describes that the distribution of MDR pathogens is very heterogeneous and may not be present in all patients who qualify the definition of HCAP (Table 56.3).[10] Local epidemiological studies need to be done to identify infecting microorganisms in specific settings.

Empiric antibiotic treatment should be patient specific based on the individual risk factor, comorbidities and local microbiological epidemiology. Broad-spectrum empiric antimicrobial regimen should be started in patients with suspected MDR risk factors (Table 56.4).

TABLE 56.3: Some of the important pathogens responsible for nosocomial pneumonias

Non-MDR pathogens	*MDR pathogens*
Streptococcus pneumoniae	Methicillin-resistant *Staphylococcus aureus* (MRSA)
Haemophilus influenzae	*Pseudomonas aeruginosa*
Methicillin-sensitive *Staphylococcus aureus* (MSSA)	*Klebsiella pneumoniae*
-Antibiotic sensitive GNB	*Acinetobacter baumannii*
Escherichia coli	*Legionella pneumophila*
Klebsiella pneumoniae	
Enterobacter, Serratia *Proteus spp*	

TABLE 56.4: Drugs and their dosages for non-MDR pathogens

Ceftriaxone 2 gm IV 12 hourly

Ampicillin-sulbactam 3 gm IV 6 hourly

Piperacillin-tazobactum 4.5 gm IV 6 hourly

Levofloxacin 750 mg IV OD

Moxifloxacin 400 mg IV OD

Ertapenem 1 gm IV OD

Drug Regimen for MDR Pathogens (Table 56.5)

A combination regimen containing at least three drugs has to be given for patients with late onset VAP/HAP and HCAP (all cases) so, as to provide a broad spectrum antimicrobial cover, i.e. two broad-spectrum drugs with anti-pseudomonas cover and one drug with MRSA cover:

1. Anti-pseudomonas agent:
   Carbapenems: Meropenem, doripenem, imipenem
   Third-generation cephalosporin: Cefoperazone-sulbactam, cefepime, ceftazidime
   Beta-lactam antibiotics: Piperacillin-tazobactam, ticarcillin- clavulanic acid
2. Anti-pseudomonas agent: Can use either a Fluoroquinolone (FQ)/aminoglycoside
   Fluoroquinolone: Levofloxacin, ciprofloxacin
   Aminoglycoside: Gentamicin, tobramycin, amikacin
3. Anti-MRSA (Methicillin-resistant *Staphylococcus aureus*) agent vancomycin/linezolid

Newer drugs for MRSA like oritavancin, dalbavancin and telavancin have been developed, which need to be studied in larger cohort of patients. Colistin has now been used to treat MDR pathogens.

However, recent evidence does not advocate combination drug therapy for all patients with HCAP.[11]

TABLE 56.5: Drugs for MDR pathogens

		Group	*Drug and Dosage*
ANTIPSEUDOMONAS	1.	Carbapenem	Imipenem 0.5 gm 6 hourly or 1.0 gm IV 8 hourly Meropenem 1 gm IV 8 hourly
		or	Doripenem 0.5 gm IV 8 hourly
		Third-generation cephalosporin	Cefoperazone-sulbactam 2 gm IV 8 hourly–12 hourly Cefipime 1–2 gm IV 8–12 hourly
		or	Ceftazidime 2 gm IV 8–12 hourly
		Beta-lactam antibiotics	Piperacillin-tazobactam 4.5 gm IV 6–8 hourly Ticarcillin-clavulanic acid 3.2 gm IV 6 hourly
DRUGS	2.	Fluoroquinolone	Ciprofloxacin 400 mg IV 8 hourly
		or	Levofloxacin 750 mg IV OD
		Aminoglycosides	Amikacin 20 mg/kg weight IV OD Gentamicin 7 mg/kg IV OD Tobramycin 7 mg/kg IV OD
MRSA	3.	Glycopeptides	Vancomycin 15–20 mg/kg actual body weight BD (max 30 mg/kg as loading dose)
		Streptograminins	Linezolid 600 mg IV 12 hourly

Patients should be treated for MDR pathogens, if two out of three risk factors are present—[severe illness (requiring mechanical ventilation or ICU care), prior antibiotic therapy (for three days in the preceding six months) and poor functional status (ADL score>12.5)]. Limited spectrum therapy for non-MDR pathogens will suffice if these risk factors are not present. These guidelines are based mainly on consensus as there is not sufficient evidence as to whether combination therapy/monotherapy is effective. Most importantly, antimicrobial therapy has to be tailored according to local microbiological flora and their antibiotic susceptibility. Each ICU/hospital should have a protocol according to this data.

Till date, no regimen has been shown to be superior over the other. A recent meta-analysis showed no difference in the mortality and treatment failure in single versus combination therapy group concluding that single agent therapy is not inferior to combination therapy.[12] In places with high risk of pseudomonas aeruginosa and other gram-negative bacilli, local microbiological bacterial susceptibility pattern should be taken into consideration before starting empirical regimen. Institution-specific guidelines should be developed taking all these factors into account.

In a broader view for patients with early onset VAP/HAP at places where there is no increased incidence of MDR pathogens, cover should be provided for *Streptococcus pneumoniae*, *Haemophilus influenzae*, Methicillin-sensitive *Staphylococcus aureus* (MSSA) and the usual community acquired pathogens with beta-lactam and beta-lactamase inhibitor combinations (piperacillin-tazobactam, ampicillin-sulbactam), ceftriaxone, fluoroquinolones (levofloxacin and moxifloxacin) and doripenem.

For patients with late onset VAP-HAP and HCAP, combination therapy is preferable. Proposed benefits of combination therapy are prevention of emergence of antimicrobial resistance, synergism of antibiotics and for providing a broader cover for all MDR pathogens.

In addition to the appropriateness of the antibiotic therapy, there are various other host and antibiotic factors, which can lead to treatment failure.[13]

Host Factors: Many of the critically ill patients have increased third space volume secondary to hypoalbuminemia and excessive fluids, which these patients receive to correct their hypotension. The consequence of the increased third space volume is a decrease in plasma drug concentration. Hypoalbuminemia also leads to increased free drug levels, which can lead to accelerated clearance of the drug, thereby decreasing the drug $t_{1/2}$.

Antibiotic Factors: The pharmacological action of various antibiotics can be classified as either time-dependent or concentration-dependent (Table 56.6). Time-dependent antibiotics are best administered in multiple-doses as continuous infusions. These antibiotics require certain time more than Minimum Inhibitory Concentration (MIC) between doses, which usually range from 40 to 50% for their best action. It varies for different antibiotics, e.g. 30 to 40% for carbapenems and 50% to 70% for cephalosporins. On the other hand, concentration-dependent antibiotics are best administered as single daily dosage. These antibiotics require attainment of the peak concentration, many times higher than the MIC for their microbiological action, and have prolonged Post-Antibiotic Effect (PAE), which makes them effective even after their drug concentration falls below MIC.

TABLE 56.6: Various antibiotics based on time or concentration dependence

Time-dependent antibiotics	*Concentration dependent antibiotics*
Penicillins Cephalosporins Carbapenems Vancomycin, Linezolid	Fluoroquinolones-Levofloxacin Aminoglycosides

Response to Therapy

Response to therapy occurs in 48–72 hours in most (75%) of the patients who respond. Response can be assessed by the improvements in fever, oxygen requirement, tracheal secretions, leukocytosis and radiological picture. Most importantly, the fever and oxygen requirements improve after 48–72 hours, though other things take time to improve. Radiological resolution generally lags behind, there may be an initial deterioration in the radiological picture. Radiological resolution depends on the age and the associated comorbidity, e.g. COPD. Resolution is slower in elderly, patients with COPD and in patients with associated endobronchial obstruction. The presence of the following radiological features indicates rapid deterioration:

- Multilobar involvement
- More than 50% increase in infiltrates in 48 hours
- Development of cavitary or necrotizing pneumonia
- Development of large pleural effusion.

Antibiotics should not be changed in the initial 48–72 hours unless there is evidence of progressive deterioration.

Tools to Assess Clinical Response

- Combined clinical and microbiological approach (repeating quantitative cultures)
- Clinical pulmonary infection score has been used to assess the improvement of VAP.

Absence of clinical response in patients with VAP requires to be evaluated aggressively. The following factors need to be considered in the case of nonresponse:

- Wrong organism/resistant organism: Consider mycobacteria, fungus, coexisting AIDS and other viral infection
- Wrong diagnosis: Noninfectious mimics of pneumonia, pulmonary embolism with infarct, pulmonary hemorrhage, atelectasis, ARDS or presence of neoplasm
- Complications: Empyema, lung abscess, extra-pulmonary infection (e.g. Catheter-Related Bloodstream Infections (CRBSI), sinusitis, clostridium difficile colitis).

Therapy needs to be escalated to cover resistant organisms in nonresponding patients. Some clinicians wait for the response after changing treatment whereas others proceed with additional investigations. Fiberoptic bronchoscopy or even open lung biopsy may need to be considered in a subset of nonresponding patients.

PREVENTION OF HAP AND VAP

There are multiple risk factors for VAP, which are amenable for intervention by nonpharmacological measures. All the methods, which aim at preventing HAP decrease the colonization of the upper respiratory tract, oral cavity and digestive tract, thereby preventing infection.

Decontamination with Antimicrobials

Chlorhexidine: Oral decontamination with chlorhexidine (2%) solution 15 ml four times daily till after extubation has been shown to be effective in preventing VAP.[14] The principle for this effect lies in the cidal action of chlorhexidine for the microbes residing the dental and gingival plaque. From a study on the role of whole body chlorhexidine cleansing on the rates of nosocomial infections, it was concluded that the procedure lead to the reduction of CRBSI, and blood culture contamination, but did not lead to reduction in the rates of VAP.[15]

Selective Decontamination of the Digestive Tract (SDD): SDD with topical and systemic antibiotics has been shown of modest benefit in preventing VAP, but is not favored by all in view of the emergence of the resistant organisms.[16]

Hand Hygiene

Health care personnel should wash their hands before and after coming in contact with patients. They should use alcohol-based solutions for washing their hands and prevent cross-infection between patients. Hand hygiene is one of the most important and effective steps to prevent nosocomial infection. Peter Pronovost has introduced a simple checklist, which has significantly reduced the incidence of central line associated infections and deaths.[17] This checklist includes five things to adhere before each central line insertion:

i. Wash your hands;
ii. Clean the patient's skin;
iii. Put on a cap, gown and mask;
iv. Avoid placing the catheter on groin; and
v. Take out lines when you do not need them.

The checklist has saved more lives than any other scientific work has done in the recent years. Some of these hold true even for HAP.

Airway

The care of the airway is important in preventing VAP. In a cost-effectiveness study, silver-coated endotracheal tubes have been shown to be effective in preventing VAP.[18] Other measure that has been shown to be effective is the Continuous Aspiration of Subglottic Secretions (CASS). Continuous aspiration of subglottic secretions use was effective in reducing the incidence of VAP to as much as half in a meta-analysis, especially in patients requiring mechanical ventilation for more than 72 hours.[19] The most commonly used CASS device is Hi-Lo Evac. This device is costlier than routine endotracheal tubes, and the cost-effectiveness has not been assessed.

Cuff Pressure

Endotracheal tube cuff pressure should be maintained between 20–30 cm H_2O to prevent aspiration of gastric and oropharyngeal contents directly into the trachea. Excessive pressures of more than those recommended will lead to tracheal mucosal injury.

Ventilatory Circuit

Care of the whole circuit that connects ventilator to the patient, including the devices like nebulizers, which are included in the circuit, is important. Regular change of ventilator circuits has not shown to decrease the incidence of VAP and is not recommended as a measure to prevent VAP.[20] One should avoid flushing of the condensate into the lower airway, which should be emptied regularly. Passive humidifiers (HME filters) are not superior to active humidifiers, as has been reported in a large systematic review.[21] Closed suctioning system has not been shown to be superior to open system in a large meta-analysis.[22] However, it seems logical to use closed systems to avoid the risk of spraying the condensate and secretions into the ICU environment. Instead, the use of Metered Dose Inhalers (MDI) may reduce the risk of VAP. The nebulizers used for delivering aerosolized medication get contaminated rapidly. Heated circuits are not superior to the unheated circuits. Heated circuits decrease the amount of condensate, but excessive heating of inspired air can lead to the drying of tracheal secretions with the impending risk of endotracheal tube blockade with secretions.

Positioning

Semi-recumbent position at 45° is effective in preventing VAP compared to supine position. Semi-recumbent position prevents aspiration and decreases the odds of developing VAP. A randomized controlled trial comparing the rates of VAP in semi-recumbent and supine position was terminated early when it was found that the rates of VAP were significantly lower in patients in semi-recumbent position.[23]

Regular suctioning of the respiratory secretions after instilling 8 ml of normal saline showed a reduction of VAP, compared to suctioning without instilling normal saline.[24]

Role of Proton Pump Inhibitors and H_2 Receptor Blockers

Proton Pump Inhibitors (PPI) and H_2 receptor blockers have been shown to increase the gastric colonization and odds of the development of VAP and HAP due to an increasing gastric pH.[25] They should be replaced by sucralfate and antacids, which do not alter the gastric pH in non-critically ill patients. The risks of stress ulcer bleed needs to be considered when stopping these agents since the risk of gastric bleeding increases with sucralfate, though not significantly.

Miscellaneous Measures

Nasogastric and nasoduodenal tubes should be removed immediately when not required in all hospitalized patients. The nasoduodenal tube feeding group has been shown to have the lower incidence of VAP and achieved nutritional goals earlier compared to nasogastric tube group.

Preventing intubation, reintubation and decreasing the duration of mechanical ventilation and using noninvasive ventilation wherever possible, can help prevent VAP.

Certain components of ventilator bundles like sedation vacation and assessment of ability to wean daily have been shown to decrease the incidence of VAP. However ventilator bundle should be hospital specific and tailored according to the available facilities.

Viral Pneumonias

Arjun Srinivasan, Ritesh Agarwal

INTRODUCTION

Community-acquired Pneumonia (CAP) is an important cause of morbidity and mortality throughout the world in all age groups. A clear understanding of the etiology is essential for the adequate management and more importantly to prevent the use of inappropriate antibiotics thereby promoting the emergence of multidrug-resistant organisms. It is also imperative to recognize viral pneumonias as antibiotics have no effect, antivirals are few with the rapid onset of resistance if misused. Viruses, especially Respiratory Syncytial Virus (RSV), influenza A and B viruses, parainfluenza viruses and adenoviruses, are recognized as important causes of CAP in children. In adults, however, viral causes of CAP are less well characterized, and specific recommendations about the assessment and management of viral CAP are sparse. Studies have been handicapped by the difficulty in isolating the viruses and due to the presence of large number of viruses with a potential to cause pneumonia. Most studies have utilized antibody detection to confirm the etiology and hence may have compromised the ability to detect viruses as the cause of pneumonia. Most reports cite an incidence of 9% to 29% viral pneumonias among all CAPs with influenza being the most common.[1,2]

RESPIRATORY VIRUSES

Viruses of importance in the respiratory tract infection include those considered to be principally the respiratory viruses, whose replication is generally restricted to the respiratory tract, and others whose respiratory involvement is a part of the generalized infection. Classification of the viruses is dependent on the type of nucleic acid core, family of the virus, protein configuration and the lipid envelope. Postinfection immunity depends on the number of antigenic sub-types in the viral family with more effective protection amongst families with multiple immunotypes like the rhinovirus or adenovirus. Immunity is also dictated by the stability of the viral antigens, the best example is that of Influenza A, which undergoes periodic minor, as well as major changes in its surface antigens leading to susceptibility to reinfection as the acquired immunity is no longer effective. Pulmonary and systemic complications of seasonal influenza contribute to the morbidity and the mortality, especially among the elderly, the immunocompromised, those with underlying chronic lung disease and cardiovascular disease.

Resurgence of interest among the medical community in viral pneumonias has been catapulted by the outbreak of Severe Acute Respiratory Syndrome (SARS) in 2003 and more recently the pandemic of novel swine origin H1N1 influenza 2009; even as we brace ourselves for the second wave in 2010 with sporadic cases being already reported from the parts of India. On the other end of the spectrum lie the viruses with the potential to cause a pandemic with even higher mortality than H1N1 2009, like the avian influenza (H5N1). Viruses like cytomegalovirus (CMV), which were considered to affect only the immunocompromised hosts, are being identified in healthy individuals with pneumonias. Cases with dramatic presentation like Hantavirus Pulmonary Syndrome (HPS), though sporadic and geographically restricted, should be considered in this era of unrestricted globetrotting.

TABLE 57.1: Important respiratory viral infections

1. Varicella pneumonia
2. Cytomegalovirus pneumonia
3. Severe acute respiratory syndrome
4. Hantavirus pulmonary syndrome
5. Adenovirus pneumonia
6. Influenza
    i. Seasonal influenza A pneumonia
    ii. Avian influenza A (H5N1)
    iii. Swine origin influenza (H1N1) 2009.

Individual viruses (Table 57.1) will be dealt with more details after an overview of the common characteristics of viral pneumonias, including similarities in clinical presentations, radiological manifestations and pathogenesis.

PRESENTING FEATURES

Pneumonia is usually a complication of descent of infection from the upper respiratory tract, and hence, patients may give history of upper respiratory tract infection, conjunctivitis or myalgia and malaise at the onset of illness or may harbor telltale signs of the same on examination. Among patients who are not overtly immunocompromised, viral pneumonias are common among the children, the elderly, the pregnant females, patients with Chronic Obstructive Pulmonary Disease (COPD) and cardiovascular disease.

Viral pneumonia in adults is usually associated with nonproductive cough, although production of frothy, pink-tinged sputum is seen in some severely ill individuals. Cyanosis, tachypnea and use of accessory muscles are red flags indicating respiratory failure on examination. Tracheal tenderness may be present, if there is associated trachietis. Chest examination may reveal only occasional rales and wheeze in spite of an extensive disease. The clinical features of sporadic cases of viral pneumonia are usually not sufficiently characteristic to permit specific viral diagnosis or differentiation from bacterial pneumonias on clinical grounds alone. Exceptions include measles and varicella pneumonia, in which the associated rash establishes the diagnosis.

The damage to the host respiratory tract is the result of direct injury by the invading virus, unregulated immune response with the release of inflammatory cytokines and blunting of local protective mechanisms like mucociliary clearance and phagocytosis. Viruses are also known to disturb the bacterial flora of the upper respiratory tract, promoting better adhesion and thereby increasing the chances of secondary bacterial infection in the immediate postviral period. Secondary bacterial pneumonias typically occur after five to seven days of the initial onset of symptoms with usually a period of apparent improvement whereas progressive viral pneumonias have a continuous downhill course. The bacteria associated are the same as in CAP with streptococcus pneumoniae, mycoplasma and *Haemophilus influenzae* being the most common. Interestingly, Community-Acquired Methicillin Resistant Staphylococcus Aureus (CA-MRSA) is increasingly being isolated unlike in bacterial CAP.

Interstitial infiltrates rather than lobar consolidation are common but findings are nonspecific to help differentiation based on chest radiograph alone. The severity of viral CAP in normal hosts is directly related to the degree and duration of hypoxemia. The magnitude of the oxygen diffusion defect caused by viral involvement of the lung interstitium in severe viral CAPs is best assessed by the Alveolar-arterial (A-a) gradient. Patients presenting with severe viral CAP typically have increased A-a gradients of more than 35. The degree of hypoxemia is related to the degree of oxygen diffusion defect caused by interstitial pathogens. Recent studies in patients of proven viral pneumonias have identified certain patterns in High Resolution Computerized Tomography (HRCT), which may help differentiate viral pneumonias from bacterial. These include multifocal consolidation, multifocal ground-glass opacities, multifocal tree-in-bud opacities and widespread bronchial wall thickening.[3-5]

Varicella Pneumonia

Varicella-Zoster Virus (VZV) causes two distinct clinical entities: Varicella (chickenpox) and herpes zoster (shingles). Chickenpox, a ubiquitous and extremely contagious infection, is usually a benign illness of childhood characterized by an exanthematous vesicular rash. Less than 20% of all cases of VZV infection occur in adults.[6] *Varicella pneumonia*, the most serious complication following chickenpox, develops more commonly in adults (up to 20% of cases) than in children and is particularly severe in pregnant women. Pneumonia due to VZV usually has its onset three to five days into the illness and is associated with tachypnea, cough, dyspnea and fever. Varicella-Zoster Virus Pneumonia (VZVP) has a reported mortality of between 2.15% and 20% in the general population, but in pregnancy, it may be as high as 41%.[7,8]

Diagnosis

Early clues to the diagnosis of pneumonia in subjects at risk are continued eruption of new lesions, persistent fever and new onset cough. The development of VZVP in the absence of fever and after the cessation of new lesion formation is exceedingly rare. Chest radiographs of VZVP typically show ill-defined nodular or reticular densities scattered throughout both lung fields. Initially, the nodules are 2 to 5 mm in diameter and are best visualized in the periphery of the lung. With progressive disease, the nodules enlarge and coalesce, forming extensive infiltrates, especially near the hila and in the lung bases.[9,10] In the milder cases, the infiltrates may resolve in three to five days. However, in widespread severe disease, the radiographic abnormalities may persist for several weeks or months. In a few patients, the lesions calcify and remain indefinitely as numerous well defined, randomly scattered, 2 to 3 mm dense calcifications in otherwise normal lung.[9,10]

Treatment

Any adult with varicella should be closely monitored for signs of respiratory difficulty and should it occur, chest radiographs and arterial blood gases should be obtained. Supportive care with oxygen by venturi mask for maintaining saturation, adequate hydration, deep venous thrombosis and stress ulcer prophylaxis should be ensured. Intravenous acyclovir in a dosage of 10 mg/kg three times a day for 5 to 10 days is effective for VZVP or other complications in adults and children, if begun early. Patients who develop respiratory failure will require invasive mechanical ventilation with protective lung ventilation strategy for maintaining saturation. Adjunctive therapy with corticosteroids was associated with decrease in duration of mechanical ventilation and accelerated physiological recovery in a retrospective analysis of 19 patients receiving mechanical ventilation in a single center.[11] A multicenter prospective study is needed before the same can be recommended for routine management.

Cytomegalovirus (CMV) Pneumonia

Cytomegalovirus DNA viruses are of the murine and human variety. Cytomegaloviruses are DNA viruses with an icosahedral capsid with 162 capsomers and the viral particles have a diameter of 120 to 200 nm. Cytomegaloviruses are members of the Herpesviridae family, which consists of eight Human Herpes Viruses (HHVs). Morphologically, CMV resembles other herpes viruses, particularly HSV, with important cytopathic differences. Although both HSV and CMV produce intranuclear inclusions, only CMV produces cytoplasmic inclusions (dense bodies).[12] Because only CMV produces perinuclear cytoplasmic inclusions, cytopathologic diagnosis is possible. Cytopathologic changes in host tissue indicate active infection. Pneumocyctis Pneumonia (PCP) and CMVs are recognized pathogens in compromised hosts, for example, in those who undergo transplants and those on immunosuppressive drugs or steroids. However, CMV, influenza (human, avian, swine) and adenovirus are the three most common causes of severe viral CAP in immunocompetent adults.

Cytomegalovirus CAP in immunocompetent hosts is uncommon but is now being recognized more frequently, particularly when presenting as severe viral CAP. As with any respiratory virus, the severity of the disease in immunocompetent individuals varies from mild flu to acute respiratory distress syndrome, requiring mechanical ventilation. Severe CMV pneumonia may initially show minimal or no pulmonary infiltrates on chest radiograph but is accompanied by varying degree of hypoxemia. Cytomegalovirus CAP has no distinct radiologic findings on chest radiograph.

It usually is necessary to rule out other causes of respiratory failure like lobar consolidation in bacterial pneumonias or other mimics of CAP. Cytomegalovirus should be included in the differential diagnosis when there are other clinical features to suggest CMV rather than other causes of severe viral CAP. Other systemic involvement, including liver, gastrointestinal tract, central nervous system and bone marrow favors CMV. The immunomodulatory effects of CMV may precipitate a flare of underlying connective tissue disease or may be the cause of deterioration thereby making management difficult, as flare requires immunosuppression versus antivirals for CMV pneumonia.

Diagnosis

Diagnosis is established most commonly by serologic testing. The diagnosis of recent CMV infection depends on demonstrating either a single elevated CMV IgM titre or a 4-fold increase in CMV IgG titres. False positive or negative serologic results can occur in the presence of other reacting antibodies like Rheumatoid Factor (RF) or antibodies against Epstein-Barr Virus (EBV). Cytomegalovirus semiquantitative antigenemia assay is a sensitive/specific and rapid method to detect CMV activation in lymphocytes. Cytomegalovirus Polymerase Chain Reaction (CMV PCR) is very sensitive and indicates reactivation of CMV in lymphocytes.

The main difficulty in using CMV PCR is that it does not distinguish between asymptomatic or latent and active infection. Because PCR is so sensitive, serial qualitative PCR, as with semiquantitative CMV antigen levels, may be more clinically useful. Importantly, in immunocompetent hosts with primary CMV pneumonia, CMV PCR is usually negative. Virus can be isolated in human fibroblast cultures, but as the cytopathic changes are slow to occur, often cultures need to be maintained for up to three weeks before they can be declared negative. The typical cytopathic change is classically described as "owl's eye" appearance and may be identified directly in tissue specimens or in cultures.

Treatment

Treatment is the only hope for cure in immunocompromised individuals, but in immunocompetent patients the decision to treat depends on the severity of infection. Patients with hypoxemia should be treated with antivirals, but prolonged therapy usually is not required. Although acyclovir is active against other herpes viruses, it is ineffective against CMV. The mainstay of anti-CMV therapy is ganciclovir 5 mg/kg (intravenous) every 12 hours for the duration of infection.

The oral equivalent of parenteral ganciclovir is Valganciclovir. Valganciclovir is metabolized to ganciclovir *in vivo* and is as effective as parenteral ganciclovir. Oral valganciclovir may be used to complete therapy after the initial ganciclovir therapy or may be used for the entire duration of therapy. The dosage of oral valganciclovir for induction therapy is 900 mg (by mouth) every 12 hours for 21 days. In immunocompetent hosts, a complete course of therapy with ganciclovir/valganciclovir is usually not necessary because patients usually improve after one to two weeks of therapy. In such patients, anti-CMV therapy is often continued for an additional week to prevent potential relapse. Foscarnet is alternative CMV therapy, but is administered intravenously and is nephrotoxic. Unlike immunocompromised host, prognosis of CMV pneumonia in normal hosts is often good.[12]

Severe Acute Respiratory Syndrome (SARS)

From November 2002 to July 2003, SARS quickly spread from Foshan (Shunde district), Guangdong Province in the People's Republic of China to 33 other countries or regions on 5 continents.[13,14] There were 8,447 cases, 21% occurring in Health Care Workers (HCWs) and 813 deaths (9.6% overall mortality) by the time SARS was contained in July 2003. The case-fatality rate in 2003 was estimated at 13.2% for patients younger than 60 years and 50% for patients more than 60 years of age. Fifty percent of patients with Acute Respiratory Distress Syndrome (ARDS) died.[13,14]

The pathogen, the human Coronavirus (CoV) group 2b, SARS-CoV, is of animal origin. The SARS-like-CoV (SL-CoV) virus from animal hosts has a nucleotide homology greater than 99% with SARS-CoV. From virus sequence data, it seems that the masked (Himalayan) palm civet (*Paguma larvata*) acted as an amplification host. The epidemic strains (including SARS-Urbani) evolved because of civet-human interaction in Chinese animal markets. Serologic evidence of natural SL-CoV infection is also found in the Chinese ferret-badger (*Melogale moschata*).[15]

The WHO case definition for probable SARS includes:

1. Fever greater than 38°C or history of fever in the preceding 48 hours.
2. New infiltrates on chest radiograph consistent with pneumonia.
3. Chills or cough or malaise or myalgia or history of exposure.
4. One or more positive tests for SARS-CoV.

As with all epidemics, during an outbreak these points are useful in screening individuals, but outside the setting suggest only presence of common flu.

During the last epidemic, most patients presented with flu like symptoms (fever, chills, cough and malaise) and two-third of them developed dyspnea and recurrent or persistent fever. Thirty percent significantly improved within one week. Advanced age, high admission neutrophil count and initial elevated Lactic Dehydrogenase (LDH) were independent correlates of an adverse outcome. Watery diarrhea was present in more than a third of the patients and was the most common extrapulmonary symptom correlated in autopsy studies by the isolation of maximum concentrations of the virus in small bowel next only to the lungs. Cardiovascular complications in the form of hypotension and unexplained tachycardia were common. Reactive hepatitis was in 24% of the patients with up to 69% developing transient elevation of liver enzymes during their course of illness. Overall subclinical infections were very few and far apart.

Post-traumatic stress disorder and other psychiatric manifestations have been reported in survivors of intensive care. Approximately one-fifth of patients presented with a normal chest radiograph, but developed infiltrates within seven days (median three days) of onset of fever. Of the 78.3% who presented with opacities on the chest radiographs, 54.6% were unilateral and the bilateral. The involvement of more than one lung zone and bilateral versus unilateral disease were associated with a higher risk of Intensive Care Unit (ICU) admission and death.[16]

Diagnosis

Sensitivity of RT-PCR collected in the first three days of the illness was inadequate. For the emergency screening of febrile patients as per protocol, the sensitivity and specificity were 92.6% and 71.6%, respectively. Confirmation of infection was made by identifying the SARS-CoV Nucleocapsid (N) protein in the serum by N antigen-capture Enzyme-Linked Immunosorbent Assay (ELISA) and N antigen-capture chemiluminescent immunoassay. Generally, in the first four to five days of illness, nasopharyngeal aspirates and throat swabs are more useful in detecting virus, whereas stool specimens are more valuable after five days of illness (20% sensitivity).

Treatment

Suspected patients must be immediately isolated using contact, droplet and airborne isolation precautions in a negative-pressure single room. Treatment is largely based on the results of uncontrolled trials as randomized controlled trials evaluating treatment regimens are not available. Early positive outcomes using ribavirin and steroids led to widespread use of that combination. In a study of 71 cases (97% laboratory confirmed); antibiotics, ribavirin plus a 3-week step-down steroid therapy and pulse methylprednisolone "rescue" resulted in 3.4% mortality, all in patients older than 65 years.[17] Various agents have shown *in vitro* activity against the virus like indomethacin, lopinavir/ritonavir. A review in 2006 of SARS therapy administered during the epidemic revealed that finding clear-cut treatment benefits was elusive. There were 26 reports of inconclusive benefits and 4 reports of possible harm related to ribavirin therapy, 25 inconclusive reports and 4 reports of possible harm from steroid therapy, and inconclusive reports for lopinavir-ritonavir therapy (2), IFN-α therapy (3) and convalescent plasma or immunoglobulin therapy (7).[18]

Hantavirus Pulmonary Syndrome (HPS)

The hantaviruses are an enveloped genus of the family Bunyaviridae. Virions are spherical and encapsulated by a bilayered phospholipid membrane. Vascular endothelial cells are the principal target, but also infect alveolar macrophages and follicular dendritic cells. Renal tubular epithelium can also be a site for infection. Genus consists of multiple viruses, which are known to cause HPS in humans. Rodents act as reservoirs, but the virus is not pathogenic to them. Transmission largely occurs through inhalation of aerosolized urine, feces, or saliva of the rodent host. HPS is most often acquired indoors as captured animals tend to have higher rates of active infection than wild ones (25% vs 10%) and humans are more likely to encounter rodent excreta in a closed environment rather than open. Most cases reported till now have been isolated or in clusters in contrast to other epidemic viruses.

The disease has four recognized clinical phases: Prodrome, pulmonary edema and shock, diuresis and convalescence.[19] Prodrome lasts for three to six days, in which phase the onset of pulmonary edema and shock is abrupt. The second phase also lasts for three to six days with maximum mortality occurring within the first 24 hours after the onset of shock. Patients who survive this phase enter a diuretic phase with urine output ranging from 300 to 500 ml/hour and this is associated with rapid resolution of respiratory symptoms. Patients then enter a phase of convalescence, which may last a few weeks to several months before complete recovery takes place. A trio of hematologic findings, including thrombocytopenia, leukocytosis with a left shift and circulating immunoblastoid lymphocytes, is unique to HPS in the United States.

Treatment

Careful history, recognizing typical phases and a high index of suspicion are essential to achieve a diagnosis in HPS. Commercial laboratories can serologically confirm or rule out the diagnosis of HPS within 24 hours; IgM antibodies to nucleocapsid antigen are universally present in symptomatic patients and IgG antibodies are present in the most. There are no specific antiviral therapies for the management of HPS as of now and the management is supportive. Patients need admission to an intensive care unit with continuous monitoring of hemodynamic status, inotropic support and invasive mechanical ventilation with protective lung ventilatory strategy. Subset of patients may benefit from Extracorporeal Membrane Oxygenation (ECMO) in centers where it is available though there are no controlled trials in the setting of HPS.

Adenovirus Pneumonia

This is one of the common viral agents causing CAP. Clinically, it cannot be differentiated from other viral pneumonias. It was first recognized to cause pneumonia among military recruits. Subsequently, outbreaks have been reported from institutionalized populations. The severity of disease ranges from mild to severe requiring hospitalization and ventilatory support. In fatal cases, there has been extensive pulmonary damage, with death occurring two to three weeks into the illness. Intravascular coagulopathy has also been a late feature of some cases and a septic shock picture has been described. Bacterial superinfection, especially secondary to *Neisseria meningitidis* may complicate the course of the disease. There are no specific therapy and involves only supportive care.

Influenza

Influenza viruses belong to the family of Orthomyxoviridae, which are lipid-enveloped, single-stranded, negative-sense, 8-segmented RNA viruses. Serotype A and B are the frequent cause of clinical disease, serotype A has multiple subtypes based on various combination of 16 known Hemagglutinin (HA) and 9 Neuraminidase (NA) genes that code for these viral envelope or surface proteins whereas B has only a single subtype. So far, only 3 subtypes of HA (H1, H2, H3) and 2 subtypes of NA (N1, N2) have caused pandemics in humans.

Traditional pandemic surveillance has focused on monitoring the antigenic shift, the reassortment of HA and/or NA genes between human and zoonotic influenza A viruses during rare events of dual infections in a human or an intermediate host. For the surveillance of currently circulating seasonal influenza viruses, most recently the A (H3N2) and A (H1N1) viruses, viral isolates are collected throughout the year to determine the most appropriate seasonal/influenza vaccine composition for the coming influenza seasons.[20] The influenza virus associated pneumonias will be reviewed in the following sections as seasonal influenza A, avian influenza and H1N1 2009 pandemic-associated pneumonias.

Seasonal Influenza A Pneumonia

Seasonal influenza results in 2,00,000 admissions and over 40,000 deaths yearly in the United States alone. Influenza activity is generally seasonal: Activity increases during the cooler months and peaks from December to March. Virus invades and attaches to the respiratory epithelial cells of the upper respiratory tract. Dissemination occurs due to the generation of droplets ranging in size from 1 to 5 micron when the patient coughs or sneezes. Incubation period is usually one to two days, but may be up to four days. Presentation is usually with fever, myalgias and rhinitis consistent with symptoms of flu. Most cases of influenza are restricted to the upper respiratory tract and have a self-limited, benign clinical course. Severe disease with primary influenza pneumonia is more common in patients older than 65 years of age, those with underlying health conditions and young children.[2] Bilateral diffuse interstitial/alveolar infiltrates were seen as the most common radiographic abnormality (52%), followed by right lower lobe consolidation (35%).

Diagnosis

Primary influenza pneumonias are difficult to distinguish from other viral, bacterial or atypical pneumonias based on clinical radiologic or laboratory alone. The duration of shedding depends on the severity of illness and age, but generally virus can be isolated from throat and nasopharyngeal swabs obtained within two days of the onset of illness. There are several modalities to document influenza infection. These include direct viral detection (antigen tests, PCR, immunofluorescence and culture) or serologic tests. Rapid viral detection in the secretions can be achieved by commercially available antigen detection kits. Viral culture is the gold standard for the detection of virus, but takes up to 48 hours to achieve diagnosis. Serologic testing requires demonstration of fourfold rise in titre and are helpful for research purpose rather than in patient management.

Treatment

Neuraminidase Inhibitors (NAI), such as oseltamivir and zanamivir have shown to decrease the duration and severity of illness, if given within 36 hours of the onset of symptoms. In complicated influenza with primary pneumonia, studies showing efficacy of antivirals in decreasing mortality or duration of illness are less convincing. In spite of this, there is a tendency to use oral oseltamivir in patients with pneumonia and ARDS. Another member of the NAI group, peramivir, is still in clinical trials. Peramivir has an advantage over oseltamivir (taken orally) and zanamivir (taken by inhalation) as it can be given intravenously. Management is usually supportive with mechanical ventilation for respiratory failure and surveillance for the evidence of secondary bacterial pneumonia and early institution of appropriate antibiotics. Yearly vaccination has shown to decrease the incidence and severity of influenza and should be encouraged in patients over 65 years of age or in the presence of co-morbid conditions.

Avian Influenza A (H5N1)

A zoonotic virus, avian influenza A (H5N1) emerged for the first time in Hong Kong in 1997 from chickens to infect humans, infecting 18 people and killing 6 of them, a high mortality rate of more than 30%.[21] As of 2009, the World Health Organization (WHO) has reported 440 cases of sporadic H5N1 human infection, of which 262 were lethal (a 60% case-fatality rate).[22] Different viral subtypes have varied ability to cause disease in human population. Though the cases of H5N1 have been sporadic and infective potential low, fear stems from the high mortality rate among infected individuals and demonstration of certain strains of low infectivity can rapidly mutate (within six to nine months), if allowed to circulate freely among poultry to become highly virulent. The incubation period for this virus has been estimated to be up to seven days, but is more commonly two to five days after the last known exposure to sick or dead poultry. In cases where human-to-human transmission was suspected the incubation period was estimated to be between 2 and 10 days.

Diagnosis

Common laboratory findings in patients with A (H5N1) infection at the time of hospital admission included leukopenia, lymphopenia and mild-to-moderate thrombocytopenia. No distinct radiological findings help differentiate it from other viral infections. Acute respiratory distress syndrome complicated 76.5% (13 in 17) of cases in Thailand and 44.4% (8 in 18) of cases in Hong Kong.[23] Multiple organ failure, with the signs of renal dysfunction and sometimes cardiac compromise, was often noted. In fatal cases, the median time from onset to death was nine days.[24]

Treatment

High degree of resistance to amantadine has made it obsolete, NAI have been used for the treatment. Antivirals should be started within the first 48 hours before the efficacy declines. The mainstay and most effective approach to treating the disease is similar to most viral pneumonias and involves good supportive care. Intensive care during critical period of multi-organ dysfunction goes a long way in improving outcome. Adjuvant therapy with corticosteroids is not proven to improve outcome and hence is not routinely recommended.

Swine Origin Influenza (H1N1) 2009

The world witnessed the first influenza pandemic in nearly 40 years in 2009. What started as an outbreak in Mexico, soon spread to engulf the whole world with cases reported from nearly all countries by early 2010. By WHO estimates, more than 17,700 deaths among laboratory-confirmed cases had been reported by March 2010. As with any pandemic, the reported cases may have formed merely the tip of the iceberg with many subclinical cases never being reported to the health care provider.

The pandemic A (H1N1) virus originated from the triple-reassortment swine influenza (H1) virus circulating in North American pigs.[25,26] Complete genome sequencing has shown that the known molecular markers of pathogenicity (PB1-F2 and nonstructural-1 proteins) are not expressed in the pandemic A (H1N1) virus.[27] Animal studies have shown that the novel influenza virus caused increased morbidity, replicated to higher titers in lung tissue, and was recovered from the intestinal tract of intranasally inoculated ferrets in contrast to seasonal influenza H1N1 virus. This may explain why the novel virus is relatively more pathogenic than seasonal influenza viruses in its capacity to invade the lower respiratory tract and cause rapidly progressive pneumonia in humans because of our lack of background immunity to the former.

RISK FACTORS AND FEATURES OF SEVERE DISEASE

Unlike the seasonal flu, up to 40% of the patients who required hospitalization or died were previously healthy. Surprisingly, the elderly (> 65 years) are less frequently infected by the novel virus, probably because of some preexisting cross-reactive immunity against the virus due to their past exposure to previous circulating seasonal influenza A (H1N1) strains similar to the current pandemic A (H1N1) virus. Whether the components of vaccine against seasonal flu confer any cross immunity against the pandemic strain is unclear. The risk factors for severe disease include obesity, diabetes mellitus, and chronic respiratory, cardiovascular and kidney diseases, as well as diseases related to smoking, pregnancy, immunosuppression and delay in diagnosis. Diffuse alveolar damage, necrotizing bronchiolitis and diffuse alveolar damage with intense alveolar hemorrhage have been the distinct pathologic findings observed in patients who had died from H1N1 pan-demic.[28] Secondary bacterial infections were documented in 14% to 29% of patients with severe disease and require early detection with appropriate management.[29,30]

The principal clinical syndrome leading to hospitalization and intensive care is diffuse viral pneumonitis associated with severe hypoxemia, ARDS, and sometimes shock and renal failure. This syndrome has accounted for approximately 49% to 72% of ICU admissions for 2009 H1N1 virus infection.[31] Rapid progression is common, typically starting on day four to five after the onset of illness and intubation is often necessary within 24 hours after admission. Median duration of ICU care was seven days and mechanical ventilation eight days.[31] Mortality among mechanically ventilated patients ranged from 14.3% in Australia to 41.4% in Mexico[32] where access to rescue therapy were not freely available. Mortality rate among confirmed cases of H1N1 admitted at this institute in Chandigarh in 2009 was 42% (55 deaths among 131 admissions). Majority of the deaths (89.1%) occurred in the 18 to 65 years of age group with a median age of 31.5 years. The mortality among patients, receiving mechanical ventilation, was 83.1% (54 deaths out of 65) and probably represents the trend that was seen in the rest of the India during the same period.

Radiographic findings commonly included diffused mixed interstitial and alveolar infiltrates, although lobar and multilobar distributions occur, particularly in patients with bacterial coinfection (Fig. 57.1). Chest computed tomography has shown multiple areas of ground-glass opacities, air bronchograms and alveolar consolidation, particularly in the lower lobes (Fig. 57. 2).

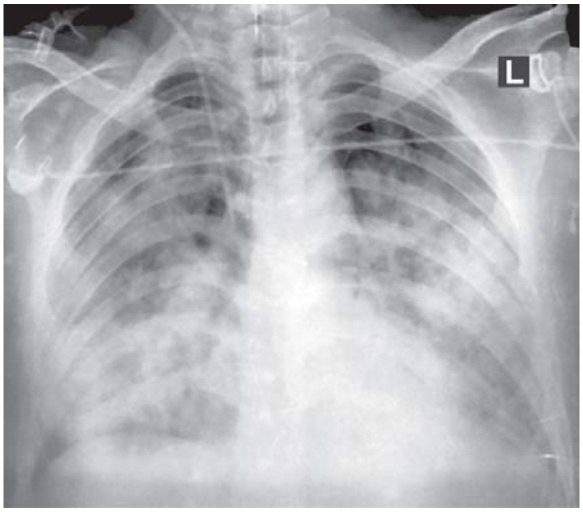

Fig. 57.1: Chest radiograph of a patient with proven severe H1N1 infection presenting with ARDS

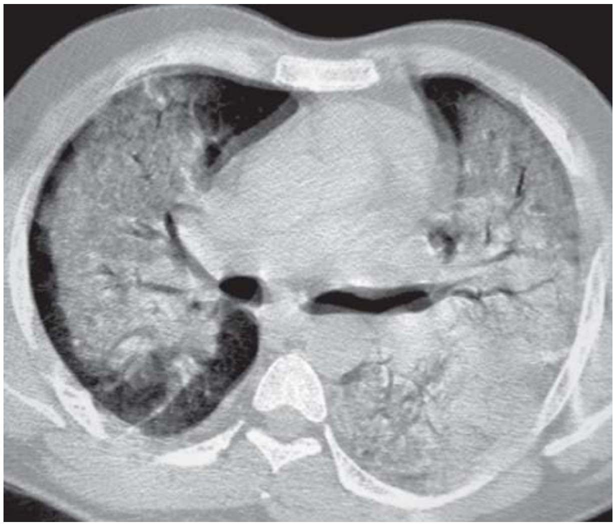

Fig. 57.2: CT of the same patient showing extensive areas of consolidation

Pulmonary thromboembolism has been reported in critically ill patients in spite of prophylaxis. Laboratory findings at presentation in patients with severe disease typically include normal or low-normal leukocyte counts with lymphocytopenia and elevations in the levels of serum aminotransferases, Lactate Dehydrogenase (LDH), creatine kinase and creatinine. Elevated creatine kinase, LDH, creatinine, metabolic acidosis and thrombocytopenia portends poor prognosis.[33] Few cases of encephalitis and myocarditis have been reported.

RESPIRATORY PROTECTION FOR HEALTH CARE PROFESSIONALS

Standard and Droplet Precautions are considered adequate to control the transmission of influenza in most health care situations. Vaccination of health care staff against seasonal and pandemic influenza strains is an essential protective strategy, but may be difficult to incorporate in practice as even with seasonal influenza the compliance among health care professionals for vaccination is only about 40%. Management principles include: Performance of hand hygiene before and after every patient contact or with the patient environment, disinfection of the patient environment; early identification and isolation of patients with suspected or proven influenza; adoption of a greater minimum distance of patient separation (2 meters) than previously recommended; use of a surgical mask and eye protection for personal protection on entry to infectious areas or within 2 meters of an infectious patient.[34]

The Centre for Disease Control (CDC) recommends the use of N95 respirators in only people involved in aerosol generating procedures like suctioning or bronchoscopy. Prophylactic antivirals should be restricted to individuals with sustained and heavy exposure. In high aerosol-risk settings, use of particulate mask, eye protection, impervious long-sleeved gown and gloves donned in that sequence and removed in reverse sequence, avoiding self-contamination should be practiced. Symptomatic staff should be excluded from discharging duties till such time criteria for non-infectivity are met. These simple precautions go a long way in conferring protection, especially in a resource constrained setting like ours.

Diagnosis

Viral RNA detection by conventional or real-time Reverse-Transcriptase–Polymerase-Chain-Reaction (RT-PCR) assay remains the best method for the initial diagnosis of 2009 H1N1 virus infection. Nasopharyngeal aspirates or swabs taken early after the onset of symptoms are suitable samples, but endotracheal or bronchoscopic aspirates have higher yields in patients with lower respiratory tract illness. Consequently, negative results in single respiratory specimens do not rule out 2009 H1N1 virus infection and repeated collection of multiple respiratory specimen types is recommended when clinical suspicion is high. Commercially available rapid influenza detection kits have poor sensitivity and cannot differentiate H1N1 2009 from seasonal influenza. Virus can be isolated in various cell cultures, but usually takes several days for diagnosis.

Antiviral Therapy

H1N1 2009 is susceptible to neuraminidase inhibitors, such as oseltamivir and zanamivir, but is almost universally resistant to amantadine and rimantadine. Early institution of oseltamivir results in the reduction of duration illness, severity and clearance of virus from the upper respiratory tract. Progression of disease and death can occur despite early therapy and even administration of oseltamivir after 48 hours of the onset of symptoms have been associated with reduced mortality among hospitalized patients. One should not wait for test results for starting antivirals and even if negative, should be continued on oseltamivir until an alternate diagnosis is achieved. In severely ill patients, viral RNA may be detectable in endotracheal aspirates for several weeks after the initiation of oseltamivir therapy.

An increased dose of the drug (e.g. 150 mg twice daily in adults) and particularly an increased duration of therapy (e.g. a total of 10 days) with the avoidance of treatment interruptions are reasonable in patients with pneumonia or evidence of clinical progression. A *His275Tyr* mutation in viral neuraminidase confers high-level resistance to oseltamivir, but not to zanamivir. Most oseltamivir-resistant 2009 H1N1 viruses have been sporadic isolates from treated patients, particularly those with immunosuppression who received prolonged oseltamivir therapy or those in whom post-exposure oseltamivir chemoprophylaxis failed, but few cases of *de novo* resistance have been reported, which is a cause for concern.[35] Inhaled zanamivir has not been adequately studied in influenza, but it is the only drug that can be used in oseltamivir resistance.

Intravenous peramivir and zanamivir have shown good efficacy in seasonal influenza, but *His275Tyr* mutation also confers resistance to peramivir. Intravenous zanamivir is the drug of choice in the presence of oseltamivir resistance. Food and Drug Administration (FDA) recently approved intravenous peramivir for emergency use in hospitalized patients.

Management of Critically Ill Patients with H1N1 Influenza 2009 (Table 57.2)

Severe respiratory insufficiency necessitating mechanical ventilation was encountered in 10% to 30% of hospitalized patients with H1N1 influenza 2009.[36] Noninvasive Positive Pressure Ventilation (NPPV) relieves hypoxemia, decreases work of breathing and therefore tachypnea, but does not alter the course of

TABLE 57.2: Management of critically ill H1N1 influenza 2009 patients

Definite benefit in all critically ill patients	*Benefit in subgroup of patients not responding to standard care*	*Potential or unproven benefit*
Oseltamivir, zanamivir	Activated protein C	Pooled hyperimmune serum
Low tidal volume ventilatory strategy and conservative fluid management.	ECMO, high frequency oscillatory ventilation, prone ventilation	Noninvasive positive pressure ventilation (NPPV)
DVT and stress ulcer prophylaxis.	Recruitment maneuvers	IvIG, statins and N-acetyl-L-cysteine
	Corticosteroids in shock and persistent ARDS	Corticosteroids upfront in the absence of shock

illness. As with other cases of ARDS, NPPV is not routinely recommended for the management of hypoxemic individuals as it may delay intubation and inadvertently increase mortality. Noninvasive Positive Pressure Ventilation may be used under controlled circumstances, with the knowledge that most people would require invasive ventilation and early decision to intubate, if no improvement occurs in the first hour.

The WHO interim guidelines on the prevention and control of acute respiratory diseases in healthcare have included NPPV among those aerosol generating procedures in which there is possibly increased risk of respiratory pathogen transmission. Invasive Mechanical Ventilation (IMV) should be with low tidal volume (6 ml/kg IBW), lung protective ventilation (plateau pressures < 30 cm H_2O)[37] and conservative fluid strategy.[38] In ICUs where the infrastructure is available, Extracorporeal Membrane Oxygenation (ECMO) has been shown to improve survival in patients with refractory hypoxemia.[31,39]

Deep Venous Thrombosis (DVT) prophylaxis with subcutaneous heparin and stress ulcer prophylaxis should be given to all critically ill patients, unless contraindicated. Corticosteroids have not shown to improve survival, carry risk of increased viral replication, dissemination and prolonged shedding when given early in the course of illness. Steroids in stress dose (hydrocortisone 200 to 300 mg/day) should be given in the presence of co-existent shock and may be considered in patients with persistent ARDS (no improvement in lung injury score after day seven). Activated Protein C (APC) should be considered early in patients with more than two organ system involvement or a baseline APACHE score more than 25. Immunomodulation with statins, use of convalescent hyperimmune serum, intravenous immunoglobulin and N-acetyl-L-cysteine have a potential for improving outcomes in patients with severe disease, but are not of proven value to merit their usage in practice at this point of time.

TABLE 57.3: Priority groups for vaccination against H1N1 influenza

- Healthcare professionals and paramedical staff
- Pregnant women
- Individuals between 6 months to 24 years of age
- Those above 25 years of age with underlying cardiopulmonary disease, diabetes mellitus and renal disease
- Household contacts of infants younger than 6 months of age.

H1N1 Influenza 2009 Monovalent Vaccine

Greenberg et al. and Clark et al. established the efficacy of monovalent vaccine against H1N1 influenza 2009 in two separate trails published recently. There has been ambiguity regarding the dosage of vaccine (15 vs 7.5 microgram) and whether one or two doses are needed for adequate immune response. Based on the pandemic proportion of the current influenza, time needed for eliciting immune response and need versus availability of vaccine, it is been recommended that a single dose of 15 microgram of monovalent vaccine should elicit seroprotective levels of antibodies in at least 80% of recipients. CDC recommends vaccination for the defined groups of individuals (Table 57.3).[40]

Pulmonary Manifestations of Human Immunodeficiency Virus (HIV) Infection

Zarir F Udwadia

INTRODUCTION

Ever since the first description of the Human Immunodeficiency Virus (HIV) infection, the lung has been the most commonly affected organ. Early autopsy studies in the mid-eighties showed that there was pulmonary involvement in 90% of Acquired Immunodeficiency Syndrome (AIDS) patients with a widespectrum of infectious and noninfectious complications. Both HIV1 and HIV2 have been isolated from the lung, it is clear that the lungs are an important organ of viral replication. There is a widespectrum of pulmonary problems encountered in HIV (Table 58.1). The type of complication depends upon several factors related to the host, the organisms and the environment (Table 58.2). (Details of individual problems are available in the respective chapters on the subjects).

TABLE 58.1: Important pulmonary complications observed in HIV-infected patients

1. Respiratory infections
    - i. BACTERIAL:
        - *M.tuberculosis*
        - *Strep. pneumoniae*
        - *H. influenzae*
        - *Staph. aureus*
        - *Nocardia,*
        - *Listeria*
        - *Klebsiella spp*
        - *Pseudomonas spp*
        - *Rhodococcus equi*
    - ii. FUNGAL:
        - *Pneumocystic jiroveci*
        - *Cryptococcus neoformans*

Contd...

Contd...

        - *Histoplasma capsulatum*
        - *Candida albicans*
        - *Coccidioides immitis*
        - *Aspergillus spp*
    - iii. PARASITIC:
        - *Toxoplasma gondii*
        - *Cryptosporidium spp*
        - *Microsporidium spp*
        - *Leishmania spp*
        - *Strongyloides spp*
    - iv. VIRAL:
        - Cytomegalovirus
        - Herpes simplex
        - Varicella zoster
        - Epstein-Barr virus
        - Human Herpesvirus Six (HHV-6)
        - JC virus
        - Respiratory Syncytial Virus (RSV)
        - Human Herpesvirus 8 (HHV-8) (KSAHV)
2. Malignancies
    - Kaposi's sarcoma
    - B-cell lymphoma
    - Bronchogenic carcinoma
3. Idiopathic
    - Interstitial lung disease (Lymphocytic interstitial pneumonia, nonspecific interstitial pneumonia)
    - Airway disease; bronchiolitis, emphysema
    - Diffuse infiltrative CD8 lymphocytosis
    - Sarcoidosis
    - Organizing pneumonia
    - Primary pulmonary hypertension
    - Alveolar hemorrhage

TABLE 58.2: Factors on which the type of pulmonary disease in the HIV +ve patient depends

1. Geographical distribution
2. Severity of immunocompromise
3. Use of disease (such as Pneumocystis jiroveci) prophylaxis
4. Use of anti-retrovirals (ARVs).

Indian Epidemiology

Data from India on pulmonary complications in HIV patients is limited. An early autopsy study showed that tuberculosis accounted for 61% of all pulmonary diseases while bacterial pneumonias featured second at 18% in the terms of frequency.[1] In this study, Pneumocystis Jiroveci Pneumonia (PJP) infection accounted for only 5% of all cases. A more recent study of all hospitalizations for HIV in a tertiary center in Mumbai for over two years (2002-2003), which looked at 300 consecutive HIV-positive admissions revealed that the lungs were most commonly affected (120 of 300 admissions, 40%). In this study, tuberculosis (pulmonary and extrapulmonary) was the most common pulmonary cause of admissions (40%). The novel information that emerged from this study was that Pneumocystis Carinii Pneumonia (PCP), previously considered rare in the Indian context, ranked second in importance in this study (30%). Bacterial infections (pneumonia) ranked third with 30 cases (25%). Malignancies and miscellaneous conditions accounted for 4% each.[2]

PNEUMOCYSTIS JIROVECI PNEUMONIA (PJP)

The long-standing controversy about whether to place PCP in the parasitic or fungal families was finally settled by elegant gene sequencing studies by Edman incontrovertibly linking PCP to the fungal family.[3] The term PCP was subsequently changed to Pneumocystis Jiroveci Pneumonia (PJP) after the name of Czech parasitologist, Otto Jírovec. The new name first proposed by Frenkel, has now been accepted by the Centers for Disease Control and Prevention (CDC) and the National Institutes of Health (NIH) since 2002 onwards.

Globally, PJP accounted for almost 2/3rd of the AIDS index diagnoses in the first decade of the HIV pandemic. It still remains the most prevalent Opportunistic Infection (OI) in patients with HIV. Considered rare in the Indian, Asian and African context, it was probably being under diagnosed in the developing world due to the lack of a wider availability of special diagnostic facilities like High Resolution Computed Tomography (HRCT) scanning, bronchoscopy and Bronchoalveolar Lavage (BAL) studies and special immunofluorescence staining.[4] This study not only showed it to be common when diligently searched for, but also revealed that almost half of all cases (49%) would have been missed without access to the sophisticated diagnostic techniques. Earlier deaths from diseases caused by more pathogenic organisms may also have been partly responsible for less prevalence reported from Africa and India. In this series, PJP infection occurred at a low mean CD4 count of 96.

In the developed world, whilst PJP remains one of the common opportunistic infection, there is little doubt that the incidence is declining in the West. There are two reasons for this decline: Firstly, effective Trimethoprim-Sulfamethoxazole (TMP-SMX) prophylaxis used in almost all patients with CD4 counts less than 200 who are otherwise almost nine times more likely to develop PCP; secondly, the widespread availability of Antiretroviral (ARV) therapy. PJP however retains its importance in HIV and continues to develop in patients who are unaware of their HIV status, in those with no access to care, and those who are unwilling or unable to adhere to therapy, nonresponders, or in failures with ARV therapy.

Clinical Features

Dyspnea and cough are the most common symptoms and tachypnea is the most common sign. A study from Zimbabwe established that a respiratory rate more than 40/min is the single best clinical predictor of PJP infection in HIV-positive patients.[5] Crackles and rhonchi are infrequent. Whilst hypoxia is common, it is by no means universal. In our series at Hinduja Hospital, Mumbai, India, 50% of patients had a normal SaO_2 at rest and 15% had completely normal clinical examination. The mean duration from the onset of symptoms to final diagnosis averaged as long as 30 days. In fact, the rapid onset of symptoms, high fever and rigors, which are commonly encountered in pyogenic infections are all rare in PJP.

Radiology

In the early stages, bilateral mid-zone interstitial shadows are seen. These are often subtle, normal chest radiographs have been reported in 5 to 34% of series. In our own series, 10% of patients had normal radiographs, HRCT greatly increases the diagnostic rate. The commonest CT pattern consists of the bilateral patchy areas of ground glass density, which are centrally located. Air-filled cysts or pneumatoceles may be seen in the upper lobes in approximately 10% of cases. A variety of atypical radiographic features have been reported, which include:

Upper lobe infiltrates (especially in patients on nebulized pentamidine prophylaxis), cystic changes, pneumothorax, pleural effusions, focal nodular lesions, cavitation and adenopathy. It may be pointed out that effusions, upper lobe infiltrates and adenopathy are all more often secondary to TB than to PJP especially in the India and other countries where TB prevalence is high.

Of importance is the fact that whilst the evolution of the shadows is often rapid, they are slow to resolve. In an earlier report on 104 PJP patients, only 35% of patients' radiographs had actually improved at three weeks, complete resolution had occurred in only 43% at five months.[6]

Of other diagnostic tests, LDH estimation and desaturation with exercise are both sensitive, but not specific for PJP infection. Microbiology is crucial to make a diagnosis. Sputum is often not produced, hence induced by nebulization with hypertonic saline. The yield can be improved by the examination of BAL/fluid. A transbronchial biopsy is seldom performed, but further increases diagnostic yield. The organisms are best seen on staining with Gomori methenamine, calcofluor white and immunofluorescence staining, which are sensitive and highly specific for identifying trophic and cystic forms.

Treatment

Trimethoprim-sulfamethoxazole remains the treatment of choice. Unfortunately, side effects are common at the high doses required for PJP infection. As many as 50% of patients develop major side effects, which demand temporary or permanent discontinuation of treatment.

Clindamycin plus primaquine is a reasonable alternative that is better tolerated. A large multicenter study, which compared clindamycin plus primaquine with TMP-SMX in 87 patients found it better tolerated with similar success rates.[7] Other drugs which are used include nebulized and intravenous pentamidine, dapsone and atovaquone.

Role of steroids: Steroids are unequivocally useful in moderate to severe PJP. Their use should be reserved for PJP patients who are hypoxic (PaO_2 < 70 mm Hg). Steroids are shown to reduce the rate of worsening respiratory failure and death by as much as 50% in some series. They are most effective when given within 72 hours of onset of disease. They act by blunting the inflammatory response, used in a dose of oral prednisolone 20 mg twice daily, 40 mg once daily for five days, or 20 mg once daily for 11 days.

Antiretroviral Therapy (ARV): The timing of ARV in relation to PJP is controversial. Whilst it was earlier felt best to complete the TMP-SMX therapy before commencing ARV therapy, evidence from the Adult and Adolescent Spectrum of HIV Disease Project showed that the concurrent prescription of ARV was associated with improved early survival.[8]

Outcome: There is little doubt that the outcome of PJP has improved. In the Adult and Adolescent Spectrum of HIV Disease Project, which looked at 4,412 patients with 5,222 episodes of PJP infection, survival at one year improved from 40% in 1992 to 63% in 1998, despite the emergence of antibiotic resistant PJP strains.[8] This improvement in survival is attributable to widespread use of steroids, better ICU care of these patients and earlier introduction of ARV therapy.

COMMUNITY-ACQUIRED PNEUMONIAS (CAPs)

CAPs which dominates PJP in all African and most Western series is 10 times more common in HIV-positive patients.[9] The incidence of CAP increases with declining CD4 counts. Bacteremic pneumococal pneumonia accounted for 26% of all CAPs in Nairobi.[10] Gram-negative bacilli and *Staphylococcus aureus* increase in importance as immunosuppression increases. Atypical pathogens are relatively uncommon. The mortality of CAP is approximately four times higher in HIV-positive patients. Relapses are also more frequent, occurred in 22% of Nairobi sex workers with CAP.[10] TMP-SMX prophylaxis is useful not just for PJP prophylaxis, but also for prevention against bacterial pneumonia. It was associated with a 67% reduction in the incidence of bacterial pneumonia in patients receiving this drug. Pneumococcal vaccine is recommended, but may be ineffective in preventing disease; the 23 polyvalent vaccine actually increased the risk of developing CAP.[11]

Malignancies

Lymphomas, Kaposi's sarcoma and bronchial carcinoma are the malignancies, which are more frequently reported in patients who are HIV positive.

1. *Kaposi's sarcoma (KS):* Kaposis sarcoma was one of the initial pulmonary complications. It is now known to be associated with human herpesvirus type 8 (HHV8) infection. HIV is believed to activate this virus, which lies dormant in the endothelial cells, acts as the trigger for angiogenesis, which results in the development and proliferation of this vascular tumor.[12] KS becomes

more prevalent as the CD4 declines. In the United States, it is strikingly more homosexual population. The prevalence has dropped dramatically in the Western world after the introduction of ARV therapy. KS is considered rare in India apart from a few, scattered case reports. Typical radiographic features of KS include nodules and pleural effusions. In the setting of the typical KS skin lesions, the diagnosis is often presumptive. The diagnosis can be made more definitely if similar raised purple plaques are seen on bronchoscopic examination. These lesions are highly vascular and distinctive, they are best not biopsied for the fear of bleeding. Treatment involves the combination of ARVs and chemotherapy in systemic disease.

2. *Non-Hodgkins Lymphoma (NHL):* HIV-positive individuals are almost 500 times more at the risk of developing NHL compared to the normal population. NHL too occurs with an increasing frequency as the CD4 counts reduce. Epstein Barr Virus (EBV) may be implicated in the pathogenesis of many cases.[13] In the HIV-infected patients, NHL is aggressive and usually Stage 4 at presentation. The outlook, despite aggressive chemotherapy, is poor. ARV therapy is responsible for the reducing prevalence of NHL in the developed world. ARV combined with chemotherapy has been responsible for an improved survival, which is now reported.
3. *Bronchogenic carcinoma:* HIV-positive patients are at the greater risk of developing lung cancer. Some studies suggest that adenocarcinomas are more frequent. As in NHLs, lung cancers in the HIV-positive population tend to be present in more aggressive and advanced forms. Unlike with NHL or KS, the CD4 counts tend to be well preserved in patients with HIV-associated lung cancer.[14]

Miscellaneous Nonmalignant Conditions

1. *Pulmonary hypertension:* HIV is an important cause of pulmonary hypertension. HIV infection must be excluded before a young adult is labeled to have primary pulmonary hypertension. HIV is believed to result in an increased expression of endothelin.[1] HIV-Related Pulmonary Hypertension (HRPH) can occur at all stages of HIV disease and at any level of CD4 count. Prognosis is guarded and treatment is administered as for any other patient with pulmonary hypertension, though interactions between sildenafil and protease inhibitors should be borne in mind.[15]
2. *Lymphocytic Interstitial Pneumonia (LIP):* LIP, may be EB virus related, is more common in children with HIV infection. It is now increasingly encountered in adults as well. The CT appearance with interstitial shadowing may be confused with PJP infection, however the symptoms are more insidious. Thoracoscopic biopsy is usually needed to make a definitive diagnosis. Treatment consists of a combination of ARVs and steroids.

Lung Abscess

C Ravindran, Jyothi E

DEFINITION

Latin word "abscessus" means collection of pus that has accumulated in a cavity formed by the tissues on the basis of an infectious process. Lung abscess is defined as severe, localized suppurative infection in the substance of the lung, associated with necrotic cavity formation.[1] The lesion is usually surrounded by a fibrous reaction, forming the abscess wall. Failure to recognize and treat lung abscess is associated with poor clinical outcome. The formation of multiple small (< 2 cm) abscesses is occasionally referred to as necrotizing pneumonia or lung gangrene. Both lung abscess and necrotizing pneumonia are the manifestations of a similar pathologic process. In the last two decades, the increasing use of corticosteroids, immunosuppressive agents, and chemotherapeutic drugs has changed the natural milieu of the oropharyngeal cavity and contributed to the mounting frequency of opportunistic lung abscesses.

EPIDEMIOLOGY

Lung abscesses are uncommon in the West with an incidence of 4 to 5 cases per 10,000 hospital admissions. But lung abscess continues to pose a major problem in the developing countries. In a retrospective study of 1,150 consecutive patients with thoracic and cardiovascular diseases 75 patients (16%) had lung abscess, 53 of whom were treated medically with 8 deaths, while 22 had emergency resection for massive hemoptysis with 9 deaths. The mortality from lung abscesses also has decreased, but remains between 2 and 10 percent for community-acquired lung abscess and 60 percent for hospital-acquired lung abscess.[2] Majority of patients with primary lung abscess improve with antibiotics, with cure rates documented at 90 to 95%. Host factors associated with a poor prognosis include an advanced age, debilitation, malnutrition, Human Immunodeficiency Virus (HIV) infection, or other forms of immunosuppression, malignancy and duration of symptoms more than 8 weeks.[3,4] The mortality rate for patients with underlying immunocompromised status or bronchial obstruction who develop lung abscess may be as high as 75%.[5] A retrospective study reported the overall mortality rate of lung abscesses caused by the mixed gram-positive and gram-negative bacteria at approximately 20%.[4] One hundred eighty-four patients with lung abscess, admitted to the Hospital of the University of Mississippi between 1960 and 1982, were studied and data from the different decades show a mortality rate of 22% in the 1960s, 25% in the 1970s, and 28% in 1980–1982.[6]

CLASSIFICATION

Lung abscess is considered acute if the duration of symptoms at the time of presentation is less than six weeks and chronic if it exceeds six weeks.[7] Primary lung abscesses are commonly observed in patients who are predisposed to aspiration or in otherwise healthy individuals, whereas secondary lung abscesses represent complications of a preexisting local lesion, such as a bronchogenic carcinoma or a systemic disease (e.g. HIV infection) that compromised immune function[8] (Table 59.1). In a retrospective review of 23 children with documented lung abscess, 11 cases were of primary lung abscess, and 12 of secondary lung abscess.[9]

5. Bronchial obstruction
   - Tumor
   - Foreign body
   - Stricture
6. Generalized sepsis

ETIOLOGY

Lung abscesses have numerous infectious causes[10-22] (Table 59.2). Anaerobic bacteria continue to account for most cases.[10] Aspiration lung abscesses are mostly caused by anaerobic bacteria. In one report from India, the anaerobes accounted for about 38 percent of 198 cultures from 100 patients of pleuropulmonary infections, of whom all the 13 patients of lung abscess had anaerobic infection either in isolation or along with aerobic bacteria.[11] These bacteriae predominate in the upper respiratory tract and are heavily concentrated in the areas of oral-gingival disease. Other bacteria involved in lung abscesses are aerobic gram-positive and gram-negative organisms.[12-15] Among the aerobic organisms, *Staphylococcus aureus, Klebsiella pneumoniae, E. coli* and Type III *Streptococcus pneumoniae* are frequently associated with lung abscess formation.[12-15] Rarely fungi like basidiobolus (Figs 59.1A to C) can also produce lung abscess, especially in an immunocompromised host.[16-18]

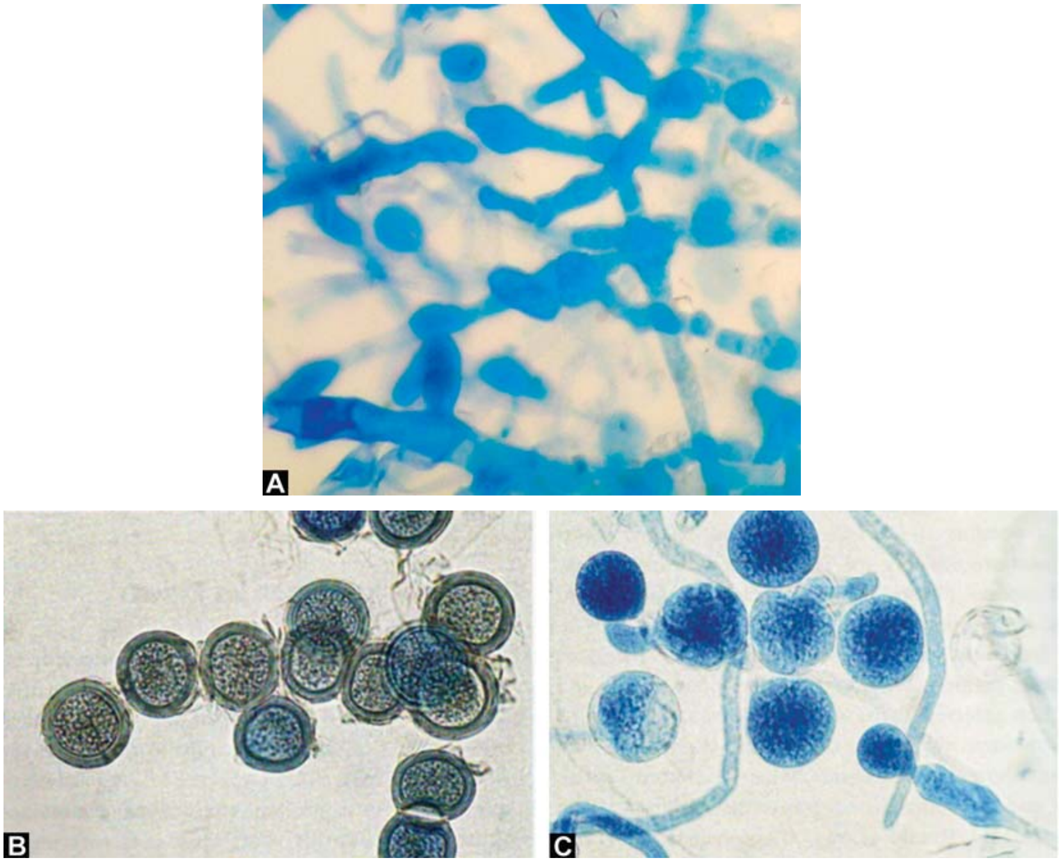
The organisms are aspirated to lower respiratory tract due to many factors, which may be local or general (Table 59.1). Other routes of the spread of infection to lungs include infected chest wall foci, infradiaphragmatic abscesses and hematogenous spread.

TABLE 59.2: Microorganisms responsible for lung abscess

Group	*Organism*
Aerobic organisms	*Klebsiella pneumoniae* *Nocardia sp.* *Pseudomonas aeruginosa* *Staphylococcus aureus* *Burkholderia pseudomallei*[19,20,21] (Fig. 59.2) *Pasteurella multocida*[22] *Streptococcus milleri* *Other streptococci*[11]
Anaerobic organisms	*Bacteroides sp.* *Fusobacterium sp.* *Clostridium sp.* *Peptostreptococcus sp.* *Actinomyces sp.* *Prevotella sp.*
Fungi	*Aspergillus sp.* (aspergillosis) *Blastomyces dermatitidis* (blastomycosis) *Coccidioides immitis* (coccidioidomycosis) *Cryptococcus neoformans* (cryptococcosis) *Histoplasma capsulatum* (histoplasmosis) *Pneumocystis jiroveci* *Rhizomucor* (mucormycosis) *Rhizopus sp.* (mucormycosis) *Sporothrix schenckii* (sporotrichosis) *Basidiobolus sp.*
Mycobacteria	*Mycobacterium avium-intracellulare* *Mycobacterium kansasii* *Mycobacterium tuberculosis*
Parasites	*Entamoeba histolytica* (amebiasis) *Echinococcus granulosus* (echinococcosis) *Echinococcus multilocularis* (echinococcosis) *Paragonimus westermani* (paragonimiasis)

PATHOGENESIS

Aspiration of infectious material is the most frequent etiologic mechanism in the development of pyogenic lung abscess. Aspiration due to dysphagia (e.g. achalasia) or compromised consciousness (e.g. alcoholism, seizures, cerebrovascular accident, head trauma) appear as important predisposing factors. Poor oral hygiene, dental



Figs 59.1A to C: Basidiobolus

infections and gingival disease are also common in these patients. Patients with alcoholism and those with chronic illnesses frequently have oropharyngeal colonization with gram-negative bacteria, especially when they undergo prolonged endotracheal intubation and are administered agents that neutralize gastric acidity. A pyogenic lung abscess can also develop from the aspiration of infectious material from the oropharynx into the lung when the cough reflex is suppressed in a patient with gingivodental disease.

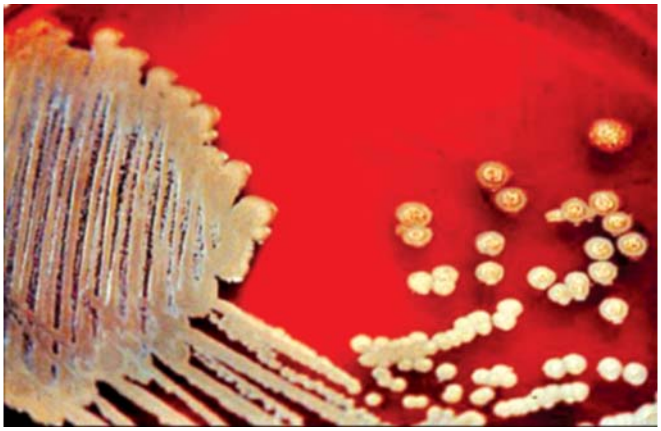


Fig. 59.2: Dry wrinkled colonies with metallic sheen of *Burkholderia pseudomallei* in blood agar

PATHOLOGY

Brock[23] in 1942, illustrated the mechanism of aspiration and abscess formation, which most often follow the dependent course. In the supine position, these are most often located in the posterior segment of the upper lobes and superior segment of the lower lobes. In the more upright position, materials flow into the basal segments of the lower lobes. When a person is in the lateral decubitus position, the axillary branches of the sub segments of apical and posterior upper lobe bronchi are favored.[24] Lung abscess that occurs as a part of hemetogenous spread may be found in any part of lung. Initially, the aspirated material settles in the distal bronchial system and develops into a localized pneumonitis. Within 24 to 48 hours, a large area of inflammation results, consisting of exudate, blood, and necrotic lung tissue. Multiple areas of liquefactive necrosis ("cross-country" pattern)[24] can occur secondary to bacterial proliferation.

This type of necrosis involves destruction of lung parenchyma, bronchi and arteries. In contrast, cavities that are more chronic and more slowly formed, such as the tuberculous cavities, often have remnants of fibrotic bronchopulmonary bands coursing through the cavity.[24] But most of the abscesses in the lung have an acute phase that destroys all the tissues in the area. Later, these areas coalesce to form a large abscess. The abscess frequently connects with a bronchus allowing drainage of the necrotic material leaving an empty or partially empty cavity with or without fluid level. The infection may extend into the pleural space and produce an empyema without rupture of the abscess cavity. The infectious process can also extend to the hilar and mediastinal lymph nodes, and these too may suppurate.

Sometimes, septic emboli may reach the lungs from right-sided bacterial endocarditis, which commonly complicates intravenous drug abuse, the usual organism being *Staphylococcus aureus*. Septic emboli may arise from the infected intravenous cannulae or from thrombophlebitis of the deep veins of the legs or pelvis or in relation to superficial cutaneous cellulitis. Gram-negative sepsis elsewhere, such as the urinary tract, the abdominal or the pelvic cavities may also contribute to the development of abscess. Alternatively, an abscess may develop as an infectious complication of a preexisting bulla or lung cyst or secondary to carcinoma of the bronchus.

CLINICAL FEATURES

Symptoms

Onset of symptoms in lung abscess is often insidious. This is more acute following pneumonia, where it begins with spiking temperature, rigors and night sweats followed by cough with sputum production. The expectorated sputum characteristically is foul smelling and bad tasting and often blood stained. Abscesses due to organisms other than anaerobes (e.g. *Mycobacteria*, *Nocardia*) do not demonstrate putrid respiratory secretions. There will be associated pleuritic chest pain and breathlessness.[25] In a series of 252 consecutive patients studied by Moreira and associates,[26] 70.2% were alcoholic. Cough, expectoration, fever and overall poor health were observed in 97% of patients, chest pain was reported by 64%, 30.2% presented digital clubbing; 82.5% had dental disease; 78.6% reported having lost consciousness at least once, and 67.5% presented with foul smelling sputum.[26]

TABLE 59.3: Differential diagnosis of a cavitary lung lesion

1. Cavitating lung cancer
2. Localized empyema
3. Infected bulla containing a fluid level
4. Infected bronchogenic cyst or sequestration
5. Pulmonary hematoma
6. Cavitating pneumoconiosis
7. Hiatus hernia
8. Lung parasites (e.g. hydatid cyst, *Paragonimus* infection)
9. Actinomycosis
10. Wegener's granulomatosis and other vasculitides
11. Cavitating lung infarcts
12. Cavitating sarcoidosis

Signs

There are no specific signs for lung abscess. Patients usually have signs of periodontal disease or a condition causing impaired consciousness. Patients are often febrile and tachypnic. Those with an abrupt onset lung abscess are often sick. Clubbing of fingers may be present, which may develop within a few weeks and this is reversible as the abscess resolves. If the abscess is localized there will be crackles on auscultation. If it is secondary to pneumonia, it is associated with dullness on percussion, bronchial breathing, egophony and crackles. There will be dullness on percussion and reduced breath sound if associated with pleural effusion. Primary lung abscesses that occur following staphylococcal suppurative pneumonia in infants and children tend to be abrupt and more threatening.[27]

Laboratory Diagnosis

A large number of conditions may present with a cavitary lung lesion (Table 59.3). Several different laboratory investigations are therefore required for the differential diagnosis of a lung abscess.

Hematological

A complete and differential white blood cell count will reveal leukocytosis and a left shift.

Microbiological Diagnosis

i. Sputum for Gram stain, culture and sensitivity. Expectorated sputum and other methods of sampling the upper airway do not yield useful results for anaerobic culture because the oral cavity is extensively colonized with anaerobes. Diagnostic material as below, uncontaminated by bacteria colonizing the upper airway may be obtained for culture[28-30] (Table 59.4).

TABLE 59.4: Uncontaminated pulmonary samples for microbiological demonstration and culture

- Transtracheal aspirate[28,29]
- Transthoracic pulmonary aspirate
- Fiberoptic bronchoscopy with protected specimen brush[30]
- Bronchoalveolar lavage fluid for quantitative culture
- Surgical specimens
- Pleural fluid (if empyema present)

ii. Bronchoscopy using a protected brush[30] to obtain a specimen uncontaminated by the upper airway or quantitative culture of organisms from the bronchoalveolar lavage fluid has been advocated to establish bacteriologic diagnosis of lung abscess. However, the experience with this technique in the diagnosis of anaerobic lung infections is limited and the diagnostic yield is uncertain.[31] But more importantly, cultures obtained by any of these methods are unlikely to be positive after the initiation of antibiotics.

iii. Blood culture: Blood cultures are infrequently positive in patients with lung abscess.

iv. If tuberculosis is suspected, acid-fast bacilli staining and mycobacterial culture also required.

v. Obtain sputum for ova and parasite whenever a parasitic cause for lung abscess is suspected.

Imaging Studies

i. *Chest radiograph:* A typical chest radiographic appearance of a lung abscess is an irregularly shaped cavity with an air-fluid level inside.[32] Lung abscesses as a result of aspiration most frequently occur in the posterior segments of the upper lobes or in the superior segments of the lower lobes (Fig. 59.3). Klebsiella lung abscess usually develops in the right upper lobe and is characterized by the bulging fissure sign. Lung abscesses due to Staphylococcus species are often multiple and bilateral. The wall thickness of a lung abscess progresses from thick to thin as it evolves. The cavity wall can be smooth or ragged, but is less commonly nodular, which raises the possibility of cavitating carcinoma. The extent of the air-fluid level within a lung abscess is often the same in posteroanterior and lateral views.[32] The abscess may extend to the pleural surface, in which case it forms acute angles with the pleural surface.[33]

Anaerobic infection is suggested by cavitation within a dense segmental consolidation in the dependent lung zones[34] (Figs 59.4 and 59.5). Lung

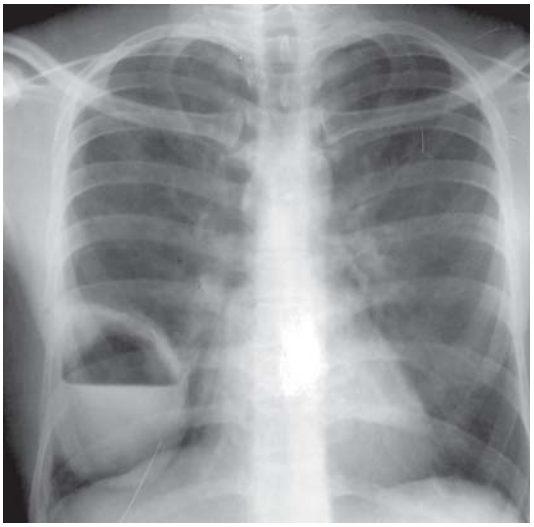

Fig. 59.4: X-ray Chest PA showing lung abscess right lower lobe

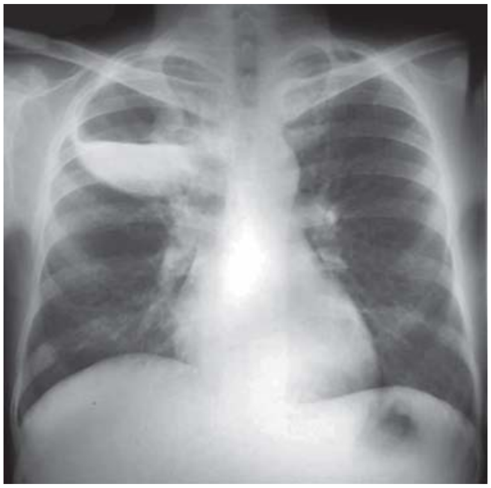

Fig. 59.3: X-ray Chest PA showing lung abscess right upper lobe

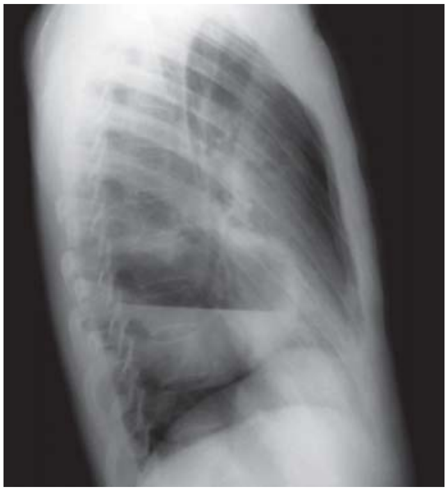

Fig. 59.5: X-ray Chest right lateral showing lung abscess right lower lobe

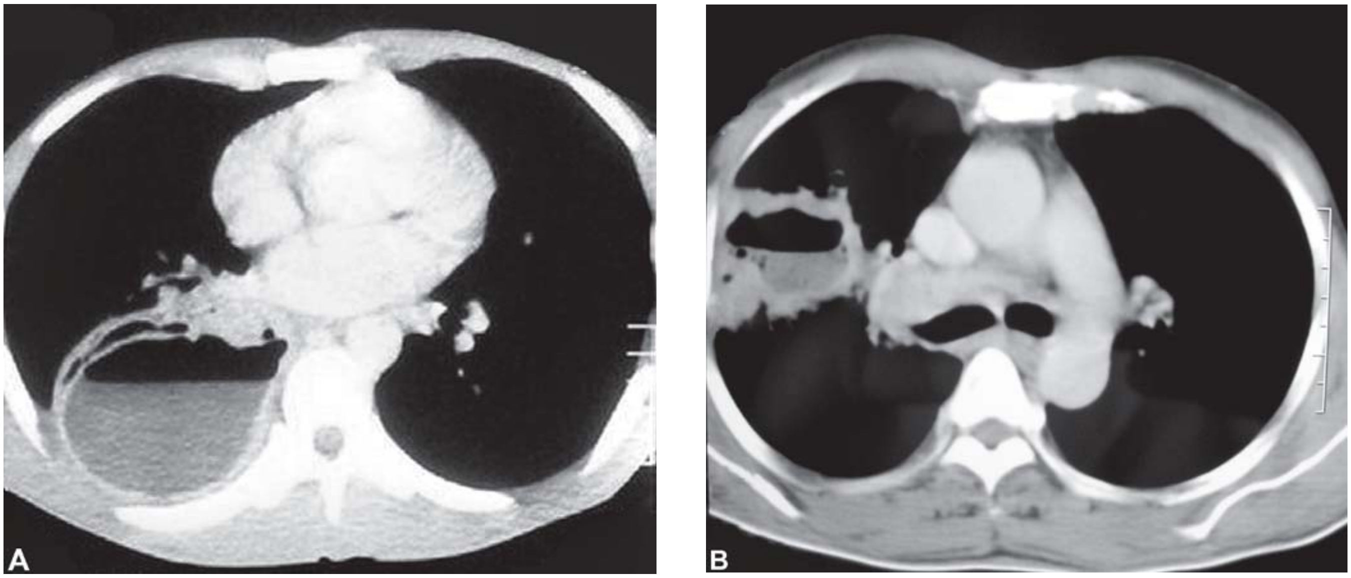

Figs 59.6A and B: CT thorax showing lung abscess

infection with a virulent organism results in more widespread tissue necrosis, which facilitates progression of the underlying infection to pulmonary gangrene. Up to one third of lung abscesses may be accompanied by an empyema.

ii. *Computed tomography (CT):* CT scanning of the lungs may help visualize the anatomy better than the chest radiography.[32] CT scanning is very useful in the identification of concomitant empyema or lung infarction.[32] On CT scan, an abscess often is a rounded radiolucent lesion with a thick wall with ill-defined irregular margins (Fig. 59.6A). Abscess walls are typically irregular in width and have regular luminal margins and exterior surfaces (Fig. 59.6B). Infected bullae may mimic an abscess especially when there is adjacent pneumonia; however, a smooth luminal margin on plain film[35] or CT suggests the correct diagnosis. The vessels and bronchi are not displaced by the lesion, as they are by an empyema.[33] The lung abscess is located within the parenchyma compared with loculated empyema, which may be difficult to distinguish on chest radiographs.[33,36] The lesion forms acute angles with the pleural surface chest wall.

iii. *Ultrasound (US) examination:* Ultrasound and ultrasound-guided transthoracic aspiration is an alternative method for CT thorax and guided aspiration. In a case series of 35 patients, 33 of the abscesses (94%) were demonstrated at ultrasound, while two lesions were not depicted. On ultrasound examination, lung abscesses were depicted as hypoechoic lesions with irregular outer margins and an abscess cavity that was manifested as a hyperechoic ring. Ultrasound-guided transthoracic needle aspiration of fluid from the abscess cavity was performed successfully in 31 of 33 patients (94%). A total of 65 pathogens were isolated from 31 aspirates (41 anaerobes and 24 aerobes).[37]

Bronchoscopy

Flexible fiberoptic bronchoscopy is performed to exclude bronchogenic carcinoma whenever bronchial obstruction is suspected or less commonly, to identify and remove a foreign body.[38] Bronchoscopy also helps to retrieve uncontaminated specimen for culture, as well as to remove pus.

COMPLICATIONS

Lung abscess if not diagnosed and treated early is met with few complications. Approximately one third of lung abscesses are complicated by empyema. This may be observed with or without bronchopleural fistula. Hemoptysis is a common complication of lung abscess. Occasionally, the hemoptysis can be massive, thus requiring urgent surgery. Spread of infection to other parts of same lung and to the opposite lung is possible. Bacteremia and metastatic abscesses, including brain abscess may also occur in patients who receive inadequate treatment. Metastatic brain abscess most frequently involve temporal lobe and cerebellum. Rarely, it may rupture into the mediastinum causing acute mediastinitis. Poor treatment response may lead on to bacteremia and septicemia.

TREATMENT

Treatment of lung abscess is guided by the available microbiology and knowledge of the underlying or associated conditions. Once the clinical diagnosis of lung abscess is made and the respiratory secretions sent for culture and drug sensitivity tests, patient should be initiated on broad spectrum antibiotics. Antibiotics with a spectrum covering gram-negative aerobes and anaerobes are preferred. This may be modified once drug sensitivity results are available.

Antibiotic Therapy

Most patients, even with necrotizing pneumonia, respond well to high-dose penicillin[39] and show clinical improvement within a week to 10 days. Clindamycin is preferred in the cases of severe underlying disease or when penicillin fails to yield signs of recovery.[40,41] The presence of empyema not only increases the duration of therapy, but also carries a higher mortality rate (20% vs 5%).[42]

- Standard treatment of an anaerobic lung infection is clindamycin (600 mg IV q8h followed by 150–300 mg PO qid). This regimen has been shown to be superior than parenteral penicillin. Several anaerobes may produce beta-lactamase (e.g. various species of *Bacteroides* and *Fusobacterium*) and therefore, develop resistance to penicillin.[43]
- Although metronidazole is an effective drug against anaerobic bacteria,[44,45] the experience with metronidazole in treating lung abscess has been rather disappointing because these infections are generally polymicrobial. A failure rate of 50% has been reported in the past.[44,45] Necrotizing pneumonia and pulmonary abscess that develop in the nursing home or in the hospital setting require a more aggressive diagnostic approach, and broad-spectrum antibiotic coverage. Inspite of these measures and appropriate antibiotic selection, nosocomial-acquired disease carries a mortality rate of 30 to 50%.[42]
- Ampicillin plus sulbactam is well tolerated and is as effective as clindamycin with or without a cephalosporin in the treatment of aspiration pneumonia and lung abscess.[46]
- Moxifloxacin is clinically effective and is as safe as ampicillin plus sulbactam in the treatment of aspiration pneumonia and lung abscess.[47]

Duration of Therapy

- Although the duration of therapy is not well established, most clinicians generally prescribe antibiotic therapy for 4 to 6 weeks.
- It generally suggests that antibiotic treatment should be continued until the chest radiograph has shown either the resolution of lung abscess or the presence of a small stable lesion.
- The extended treatment is recommended since there is a risk of relapse with a shorter antibiotic regimen.

Response to Therapy

- Patients with lung abscesses usually show clinical improvement within 3 to 4 days of initiating the antibiotic therapy. Clinical resolution is expected in 7 to 10 days. Persistent fever beyond this time indicates a therapeutic failure, and these patients should undergo further diagnostic studies to determine the cause of failure.
- Considerations in patients with poor response to antibiotic therapy include bronchial obstruction with a foreign body or a neoplasm or an infection with resistant bacteria, mycobacteria or fungi.
- Large cavity size (> 6 cm in diameter) usually requires prolonged therapy.[48]
- The infection of a preexisting sequestration, cyst or bulla may also be responsible for the delayed response to antibiotics.[49]

Physiotherapy

Physiotherapy is useful in helping the patient to clear the purulent material. Postural drainage can be given keeping the affected pulmonary segments uppermost. However, chest physical therapy and postural drainage are not widely recommended because of the fear of spillage and extension of infection.

Surgical Care

Surgery is very rarely required for patients with uncomplicated lung abscesses. The usual indications for surgery are failure to respond to medical management, suspected neoplasm or congenital lung malformation.[50] The surgical procedure is either lobectomy or pneumonectomy. When surgery is necessary, lobectomy is the most common procedure; segmental resection may suffice for small lesions (< 6 cm diameter cavity). Pneumonectomy may become necessary for multiple abscesses or for pulmonary gangrene, unresponsive to drug therapy.

Percutaneous Drainage

Percutaneous drainage of a complicated abscess (i.e. one associated with fever and signs of sepsis) is beneficial in selected patients who do not respond to adequate medical therapy.[15] They are ventilator-dependent patients who are not candidates for extensive thoracic procedures. Other indications for drainage include ongoing sepsis despite adequate antimicrobial therapy, a progressively enlarging lung abscess in imminent danger of rupture, failure to wean from mechanical ventilation, and contamination of the opposite lung. Results achieved with percutaneous drainage show it to be safe and effective method when compared with surgery. Percutaneous drainage is rarely complicated by empyema, hemorrhage or bronchopleural fistula.[51] Although, a few patients who undergo percutaneous drainage develop bronchopleural fistulas, most of these fistulae close spontaneously with the resolution of the abscess cavity. Percutaneous drainage may be used to stabilize and prepare critically ill patients for surgery. Percutaneous or surgical drainage of lung abscesses is necessary in roughly 10% of patients.[52] Aggressive interventional therapy can be diagnostic and therapeutic in the infected lung abscess. But interventional therapy can be harmful in the case of postinfectious necrotizing pneumonia.[53]

In current practice, most of the lung abscesses are drained under CT guidance. CT allows optimal placement of catheter and hence enables the safe and effective percutaneous evacuation of lung abscess. The morbidity and mortality of patients with percutaneous catheter drainage is lower than that with surgical resection.[54] Hence, CT-guided drainage should be considered the first therapeutic choice in most patients of lung abscess who do not respond to medical therapy. Endoscopic lung abscess drainage is considered if an airway connection to the cavity can be demonstrated. Success of this treatment represents an additional option other than percutaneous catheter drainage or surgical resection.[55-58] Recently the technique of passing angiography catheters through the rigid bronchoscope into the abscess cavity, to facilitate the bacteriological diagnosis and drainage of the cavity is being successfully adopted.[55,58] Endobronchial catheters with the use of laser appear to be relatively safe and effective for the treatment of lung abscess in selected patients in whom the abscess is adjacent to the central airway.[59] When necessary, a bulge in an adjacent airway can be perforated with laser.

PROGNOSIS

The prognosis of patients with lung abscesses depends on the underlying or predisposing pathologic event and the speed with which appropriate therapy is established. Negative prognostic factors include a large cavity (>6 cm), necrotizing pneumonia, multiple abscesses, immunocompromised state, age extremes, associated bronchial obstruction, and aerobic bacterial pneumonia.[3] The prognosis associated with amebic lung abscess is good when treatment is prompt.

Bronchiectasis and Cystic Fibrosis

David Honeybourne

BRONCHIECTASIS

Introduction

Bronchiectasis is a chronic condition with a variable clinical course that may include acute exacerbations and also chronic deterioration in some cases. Bronchiectasis was first described by Laënnec in 1812. Clinical features in a patient present with bronchietasis include presence of frequent productive cough often accompanied with the shortness of breath on effort. The prevalence of bronchiectasis in populations has been found to be very variable and many older studies were carried out before High Resolution Computed Tomography (HRCT) thoracic scans were available. Prevalence figures have varied between 4 per 1,00,000 population and 272 per 1,00,000 population, partly dependent upon the age range studied.[1,2] There are sparse data on the prevalence of bronchiectasis in the Indian subcontinent.

Bronchiectasis is not infrequently misdiagnosed as chronic bronchitis and/or chronic obstructive pulmonary disease with 15 to 30% of patients, diagnosed with COPD having the evidence of bronchiectasis on high resolution CT lung scans. [3,4]

There is some evidence that in populations with poor access to health care and high rates of lower respiratory tract infections, particularly during childhood, there may be a higher prevalence of bronchiectasis.[5]

Pathology

Until recently, the original definition of bronchiectasis was based on the pathological findings. Pathologically bronchiectasis is defined as permanent dilatation of the bronchi.[6] Further morphological definition has classified bronchiectasis as cylindrical or tubular, which involves dilatation of the airways and also varicose bronchiectasis. There are, in addition, focal areas of narrowing within the dilated airways. A further type is saccular or cystic bronchiectasis, which is characterized by the progressive dilatation of the bronchi with collection of large clusters of cysts. However, morphological subtyping of bronchiectasis is of little practical value in the terms of patient management. Figure 60.1 shows changes of advanced bronchiectasis.

The airways in bronchiectasis show evidence of chronic inflammatory changes with high sputum concentrations of substances such as elastase, interleukin 8 and other proinflammatory agents. It is thought that

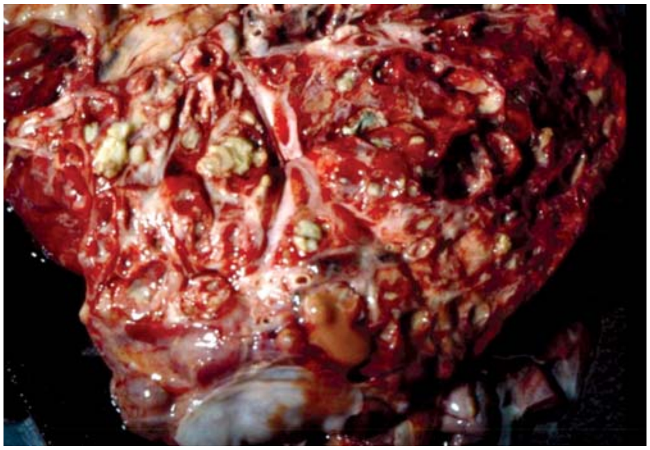

Fig. 60.1: Extensive advanced bronchiectasis

an increase in the levels of these agents is driven by recurrent bacterial infections.

Physiology

Classically, patients with bronchiectasis show the evidence of airflow obstruction. Around 40% of cases may show significant improvement in FEV_1 after using a beta-2 bronchodilator.[7] Also a significant number of patients show evidence of bronchial hyperreactivity.[8] Patients may also have a restrictive defect due to fibrotic changes associated with bronchiectasis.

Etiology

Table 60.1 shows a list of causes or conditions associated with bronchiectasis.

Childhood viral or bacterial infections particularly in malnourished children are known to predispose to lung damage within the growing lung and lead to the emergence of bronchiectasis. The increasing use of immunization against whooping cough (*Bordetella pertussis*) and measles has led to a reduction in such cases. In countries, where there is a high incidence of pulmonary tuberculosis, there are also likely to be many cases of patients with subsequent bronchiectasis secondary to fibrotic damage caused by tuberculosis. Other bacterial infections are known to be involved in both the early and later stages of bronchiectasis, e.g. *Pseudomonas aeruginosa* and *Haemophilus influenzae.*

Atypical mycobacteria are being increasingly recognized in patients with bronchiectasis and infection with these atypical organisms may initiate bronchiectasis or colonization and further tissue damage may occur in patients with preexisting bronchiectasis.

TABLE 60.1: The etiology of bronchiectasis

- Postinfectious, e.g. tuberculosis, whooping cough, pneumonia
- Cystic fibrosis
- Connective tissue diseases, e.g. SLE, rheumatoid arthritis,
- SLE, Sjögren's syndrome, relapsing polychondritis
- Allergic bronchopulmonary aspergillosis
- Ciliary defects, e.g. primary ciliary dyskinesia, Young's syndrome, Kartagener's syndrome
- Immune deficiency, e.g. IgA deficiency, X-linked agammaglobulinemia, common variable immunodeficiency, secondary to chronic lymphatic leukemia
- Congenital defects, e.g. tracheobronchomegaly (Mounier-Kuhn syndrome), pulmonary sequestration
- Secondary to inhalation or aspiration, e.g. due to a foreign body
- Inflammatory bowel disease, e.g. ulcerative colitis

Aspergillus fumigatus is commonly found in the environment and in susceptible patients, may lead to an allergic reaction, causing the clinical condition Allergic Bronchopulmonary Aspergillosis (ABPA). Allergic reactions to the fungus in the airways may cause inflammation and collateral damage to the airway walls as a result. Occasionally invasive aspergillosis may also occur.

Patients who are Human Immunodeficiency Virus (HIV) positive may also develop bronchiectasis related to their reduced immunity.

Genetic and congenital conditions may lead to bronchiectasis. These include cystic fibrosis (see later part of this chapter for further description) and primary ciliary dyskinesia. Primary ciliary dyskinesia is an inherited autosomal recessive condition with a birth frequency of approximately 1 in 30,000. In this condition bronchial cilia are unable to beat normally. This is due to an absent or shortened dynein arm within the cilia. Some of these patients also have Kartagener's syndrome where there is bronchiectasis, situs inversus and chronic sinusitis. This condition causes a lack of correct rotation of organs in the fetus and hence there is often association with situs inversus and dextrocardia. Some progress has recently been made in identifying the underlying genetic mutations. Another uncommon condition is Mounier-Kuhn syndrome, which causes tracheobronchomegaly. Bronchiectasis has also been reported to be found in associated with alpha 1-antitrypsin deficiency and Marfan's syndrome.

It is important to think of the possibility of an underlying immune deficiency causing an increased risk of lung infections leading on to the development of bronchiectasis. Such immunodeficiency disorders include X-linked agammaglobulinemia, IgA deficiency, Severe Combined Immunodeficiency of Childhood (SCID) and Common Variable Immunodeficiency (CVID).

In some subjects with bronchiectasis, there may be a history of aspiration of a foreign body, such as a peanut during childhood or sometimes aspiration of food may cause a foreign body to be lodged in an airway, which may then gradually result in the development of bronchiectasis over a long period of time. Aspiration will typically, but not invariably, involves the right middle or right lower lobe.

Bronchiectasis may be associated with connective tissue diseases especially rheumatoid arthritis, but also systemic sclerosis, systemic lupus erythematosus or ankylosing spondylitis.

Clinical evidence of bronchiectasis has been reported in around 3% of patients with rheumatoid arthritis. More detailed investigations, including high resolution CT scanning have reported much higher levels.[9,10]

There is an association between inflammatory bowel disease and bronchiectasis particularly in patients with chronic ulcerative colitis.[11] Airway inflammation may be exacerbated by effector lymphocytes. Sometimes immune modulating drugs may result in an exacerbation of lung symptoms. It is interesting that in some patients, who have a bowel resection for ulcerative colitis, the respiratory symptoms may increase postoperatively.

The proportion of bronchiectasis patients with underlying disorders detailed in Table 60.1 will vary according to the population studied. Clearly in a population, where there is a high prevalence of pulmonary TB, postinfectious bronchiectasis will be relatively common. Also, the availability of complex immune testing may be limited in some countries and therefore, this cause may remain underdiagnosed. However, in many published series, around 50% of patients with bronchiectasis will have no definite identified cause.

Bronchiectasis is often diffuse, but sometimes may be local. A good example of local bronchiectasis is the one which occurs after an inhaled foreign body and may lodge in the right middle or right lower lobe.

Cases of bronchiectasis may be identified in association with nail dystrophy often with yellow discoloration called "yellow nail syndrome" and is usually associated with sinusitis, pleural effusions and primary lymphedema.

Young's syndrome is a combination of bronchiectasis, obstructive azoospermia and chronic sinusitis.

There is some emerging evidence that there may be an association between asthma and bronchiectasis. A history of asthma usually occurs first and then evidence of bronchiectasis occasionally emerges many years later. Some of these cases may be related to ABPA.

Symptoms and Signs

Recurrent cough with sputum production may be an indication of underlying bronchiectasis in children. There should also be a high index of suspicion for underlying bronchiectasis in children with chronic respiratory symptoms. Furthermore, the finding of persisting inspiratory crackles over the lungs should raise the possibility of bronchiectasis.

In adults, similar symptoms to those in children, i.e. a chronic productive cough with shortness of breath and occasionally wheezing may occur. Also, the patient may have recurrent hemoptysis and fever at times of acute infective exacerbations. Pleuritic chest pain may also occur occasionally. Frequent respiratory infections may be associated with weight loss. Based on appearance, sputum can be classified into mucoid, mucopurulent or purulent types. A higher proportion of patients with varicose or cystic bronchiectasis have purulent sputum compared to those with tubular bronchiectasis as assessed by high resolution CT lung scans.[4]

Dyspnea correlates with the degree of impairment of FEV_1, sputum volume and extent of changes seen on HRCT scans. Dyspnea occurs in around 72% of cases.[12] Chest pains, usually nonpleuritic, may occur in around one-third of patients. Hemoptysis occurs in around half of cases and in a small proportion of cases, may be massive and life threatening.

There is, however, a form of bronchiectasis in adults where there may be daily nonproductive chronic cough. Therefore, the absence of purulent sputum production does not exclude the possibility of underlying bronchiectasis.

A full assessment of symptoms should include: An estimated or measured 24-hour sputum volume when clinically stable, a record of the number of infective exacerbations that the patient has per year, the extent of the use of antibiotics and also assessment of the effects of the symptoms on activities of daily living. The St. George's respiratory questionnaire has been used to assess the quality of life in the adult patients with bronchiectasis.[13]

Classical sign on examination is the presence of coarse inspiratory crackles over the affected lungs especially in the lower zones, which may be present in about 70% of patients. Crackles may often extend into expiration. Coughing may temporarily lessen the crackles. Wheezing may be heard in around 45% of cases. Finger clubbing has been reported to occur in around 40% cases, although this has been less frequent in some reports.[12]

Diagnosis

Prior to CT lung scanning, bronchograms were the definitive way of diagnosing and delineating the extent of bronchiectasis. The advent of HRCT lung scanning has revolutionized the diagnosis of bronchiectasis.[14] CT scanning has been shown to be the most sensitive and specific way of diagnosing the condition. In particular, the HRCT is superior to a plain chest X-ray. CT scan appearances (Fig. 60.2) may include ring-like shadows where airways are seen in cross-section or a tramline appearance where airways are seen in longitudinal section. Modern high resolution CT scanners can produce 3-D reconstruction of affected areas (Fig. 60.3).

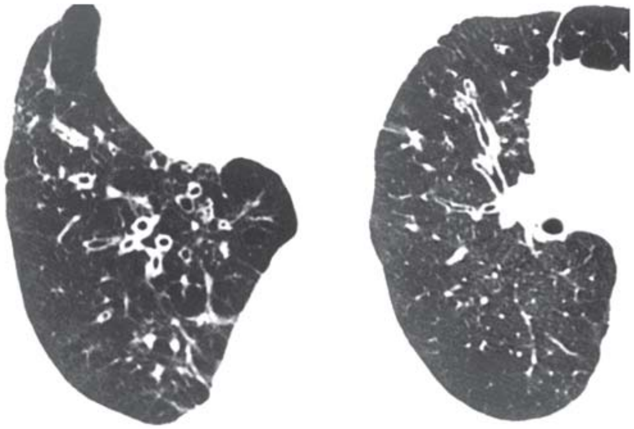

Fig. 60.2: High resolution CT scans showing the signs of signet ring shadowing and tramline changes typical of bronchiectasis

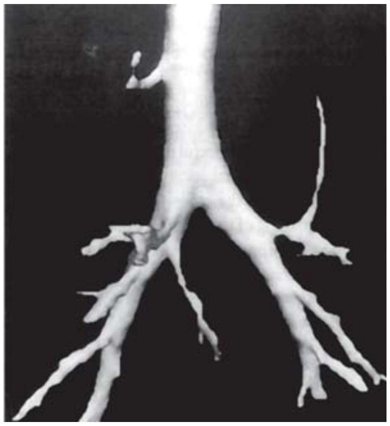

Fig. 60.3: 3-D reconstruction from a CT scan showing bronchiectasis

Nonspecific findings include focal pneumonitis or areas of atelectasis. CT scanning may also visualize varicose constrictions. The distribution of abnormalities seen on the CT scan may occasionally give some clue as to the underlying etiology. For instance, localized bronchiectasis in the right middle or right lower lobe suggests a foreign body aspiration, cystic fibrosis and ABPA, which tend to have an initial predilection for the upper lobes.

Other investigations include (after taking a careful history and performing a thorough examination) assessment of sputum samples for bacterial infections, including mycobacteria and also fungal infections such as aspergillus. The possibility of ABPA should be investigated by measuring the total serum IgE and looking for specific IgE and IgG to *Aspergillus fumigatus*. Immune deficiency may be detected by looking at serum IgG, IgA and IgM levels, IgG subclasses and also an assessment of functional antibody levels, particularly antibody levels against *Hemophilus influenzae* and *Streptococcus pneumoniae*. In some cases, investigations for possible underlying cystic fibrosis may be appropriate (see later in this chapter). In selected patients, studies of cilial function will be appropriate particularly looking for primary ciliary dyskinesia. They will usually require referral to a specialist center where mucosal biopsies are examined by ultramicroscopy. Also investigations should look for the possibility of an associated underlying connective tissue disease.

Microbiology

Patients with established bronchiectasis may have a wide range of respiratory pathogens in the sputum. Common causes of bacterial exacerbation in bronchiectasis include *Haemophilus influenzae, Staphylococcus aureus,* MRSA, *Streptococcus pneumoniae*, coliforms (e.g. Klebsiella, Enterobacter) or *Pseudomonas aeruginosa*. Assessment of sputum samples, over the course of weeks or months at clinic visits, often provides invaluable information. Patients may eventually become colonized by one or more organisms and occasionally the numbers of those organisms increases and initiates an acute exacerbation requiring antibiotics. In particular, *Pseudomonas aeruginosa* is likely to cause chronic colonization in more severe cases and may lead to progressive lung damage as part of a "vicious circle" of recurrent infection, tissue damage, predilection to further infection and then, further tissue damage. Specific treatment for chronic pseudomonas colonization is detailed below.

Specific sputum testing for mycobacteria should be carried out, firstly to exclude the possibility of tuberculosis, and secondly to look for colonization and possible infection with atypical mycobacteria such as *Mycobacterium avium-intracellulare, Mycobacterium kansasii or Mycobacterium abscessus*. The finding of atypical mycobacteria on two samples of sputum will then indicate the need for prolonged multiple antibiotic therapy.[15]

Treatment

Treatment can be divided into two areas. Firstly for an exacerbation of bronchiectasis and secondly for long-term maintenance treatment.

An exacerbation causes the patient to have symptoms of one or more symptoms such as increasing frequency of cough, sputum volume and sputum purulence. Initially the treatment depends partly on the previous microbiology results. If the patient is colonized with

Pseudomonas aeruginosa, then treatment can be done with an oral agent, such as ciprofloxacin 500 mg twice a day; for more severe exacerbations, intravenous antibiotics may be more effective. If two different types of intravenous antibiotics are used at the same time, then this will help in reducing the risk for emergence of antibiotic resistance. Also intravenous therapy would be indicated, if there was a failure of improvement on oral treatment. There are currently very few oral agents available, which are effective against *Pseudomonas aeruginosa*. Ciprofloxacin is often the first choice of oral agent and in some countries chloramphenicol is an alternative, but it needs to be explained to the patient that there is a rare possibility (approximately 1 in 25,000) of the patient developing severe aplastic anemia from the drug.

If infection is found due to other bacterial agents such as *Streptococccus pneumoniae, Haemophilus influenzae, Moraxella catarrhalis* or *Staphylococcus aureus*, then an oral agent may be sufficient, or alternatively a single intravenous agent may be effective. If the exacerbation is caused by MRSA, then often two antibiotics are recommended either orally or intravenously. (Table 60.2)

Due to difficulties with antibiotic penetration into the damaged lung and airways,[16] a prolonged course of antibiotics is often required. The optimum duration of such a course is unclear, however if there is a clinical improvement with a fall of serum inflammatory markers, such as C-reactive protein, then this would indicate improvement and often such a course of antibiotics would last for 10 to 14 days.

Another important treatment option for an exacerbation includes physiotherapy. There has been some recent evidences that physiotherapy is effective in acute exacerbations.[17] Also patients may benefit from nebulized bronchodilators during an exacerbation and may later be transferred back to regular treatment. It is unclear, whether a course of steroids given at the same time, as the course of antibiotics has any beneficial effect. Theoretically, it may reduce the inflammatory response in the lung, but the possibility of side-effects also needs to be considered.

The choice of intravenous agents for an exacerbation due to *Pseudomonas aeruginosa* includes ceftazidime, aztreonam, tazobactam, meropenem, colistin, and aminoglycosides such as tobramycin or gentamicin. Availability of these drugs will vary between different countries. If intravenous aminoglycosides are used, then monitoring of blood levels is essential to reduce the risk of renal or auditory side effects. For instance, if tobramycin is given two or three times per day then pre-dose and post-dose levels should be measured to assess the trough and peak levels. If a single daily dose of aminoglycoside is used,[18] e.g. a 30 minute infusion of tobramycin, then monitoring of just trough levels may be sufficient.

Also with acute exacerbations, it is of utmost importance to address general issues such as maintaining adequate hydration and maintaining oxygen saturation.

Noninvasive ventilation may be useful for those patients who slip into type 2 respiratory failure.[19]

Long-term Management of Stable Disease

The general advice about stopping smoking and improving nutrition applies to bronchiectasis patient. Also annual vaccination against seasonal influenza is advised as is pneumococcal vaccination, approximately every 10 years. Patients with significant bronchiectasis should receive instructions from a respiratory physiotherapist about the choice of different airway clearance techniques and should be strongly advised to carry out home physiotherapy regularly. There is currently no good evidence to use nebulized recombinant human DNase as a mucolytic agent, although further larger studies may be required.[20] There have been some studies recently looking at nebulized hypertonic saline[21] and also inhaled mannitol[22] as agents to help aid sputum production and it is likely that further evidence about their possible value will emerge in the near future. Lung function tests should be carried out before and after bronchodilators use to look for evidence of reversibility of airflow obstruction with both inhaled β-agonists and anticholinergic agents. Sometimes exercise tolerance and

TABLE 60.2: Recommendation of antibiotics to be used for these infections

Bacterial infection	*First choice*	*Second line treatment*
Haemophilus influenzae or *Moraxella catarrhalis*	Co-amoxiclav	Doxycycline, ciprofloxacin
Streptococcus pneumoniae	Amoxicillin	Clarithromycin
MRSA	Rifampicin and trimethoprim or IV vancomycin or teicoplanin	Rifampicin and doxycycline or linezolid
Pseudomonas aeruginosa	Ciprofloxacin	Ceftazidime and tobramycin or colistin

symptoms may improve with these agents despite there being no significant improvement in lung function measurements. The evidence base for using inhaled corticosteroids is limited.[23,24] There have been some studies that have shown a reduction in sputum volume and an improvement in quality of life measurements without any obvious effects on lung function or exacerbation rates. Some patients may benefit from a trial of inhaled steroids for several months.

In patients who are colonized with *Pseudomonas aeruginosa*, the use of long-term nebulized antibiotics may be helpful in reducing the bacterial load in the airways. This, in turn, may reduce chronic inflammation and hence reduce lung damage. The inhaled antibiotics, however, have the drawback of being expensive and sometimes may cause wheezing even after pre-dosing with inhaled β-2 agonists. There is some limited evidence in the literature of benefit from long-term nebulized antibiotics in patients with more severe bronchiectasis colonized with pseudomonas.[25] On first isolation of *Pseudomonas aeruginosa* in the sputum, attempts should be made to eradicate the infection to try and stop chronic colonization.

In a small number of patients with very localized bronchiectasis, the possibility of surgery should be considered.[26] They apply for instance to those patients who have localized bronchiectasis following aspiration of a foreign body or related to previous localized tuberculosis. Surgery with localized lung resection may benefit selected patients with hemoptysis, chronic debilitating cough or a lung abscess unresponsive to antibiotic treatment.[27]

Lung transplantation may also be considered, but the capacity to do this developing countries is currently very limited.

The role of long-term oral antibiotics in bronchiectasis, perhaps given as a rotation of different antibiotics, is uncertain. However, there is some evidence in the literature regarding benefit of such an approach in patients with severe bronchiectasis in terms of reduced sputum volume, number of days absent from work due to ill health and reduction in exacerbation frequency. Recently there has been some evidence of the potential benefit of reducing exacerbation frequency by using long-term oral azithromycin as an anti-inflammatory agent in bronchiectasis.[28]

Noninvasive ventilation can improve quality of life in some patients with chronic type 2 respiratory failure due to bronchiectasis.[29]

Complications

Hemoptysis is a rare, but potentially life-threatening complication of bronchiectasis. Severe hemoptysis (defined as more than 300 mls) of blood coughed up per 24 hours may occur. Whenever possible, the bleeding site should be identified by a combination of bronchoscopy, CT lung scanning and angiography. Often bleeding occurs from a bronchial artery and an interventional radiologist may be able to embolize the vessel.[30] Occasionally with severe hemoptysis, surgery may be necessary.

Amyloidosis is an occasional complication of chronic severe bronchiectasis. A lung abscess may develop due to bronchiectasis and this may be refractory to prolonged antibiotic therapy.

Prognosis

The prognosis of bronchiectasis is very variable, depending upon any underlying cause, particularly immunodeficiency, the extent of the bronchiectasis and also the type of bacterial colonization. Generally, colonization with *Pseudomonas aeruginosa* is linked to a worse prognosis.

Research into different treatments of non-cystic fibrosis bronchiectasis has lagged behind treatments for cystic fibrosis related bronchiectasis and further trials are required for new emerging drug treatments to establish whether they have a role in non-cystic fibrosis bronchiectasis.

CYSTIC FIBROSIS

Epidemiology

Cystic Fibrosis (CF) is a disease caused by an autosomal recessive mutation on chromosome 7. In UK, there are about 8,000 people who have this diagnosis (now with improved prognosis the proportion of adults is slightly higher than those in children). In European populations, CF affects approximately 1 in 2,500 live births. In some countries there is now a national screening program to detect such cases soon after birth. Again in European populations, approximately 1 in 25 live births carries 1 mutation. There is some speculation in the literature that heterozygotes may possibly have a survival advantage when faced with other gastrointestinal infections such as cholera or typhoid. This may explain why the disease has not become gradually rarer over the centuries. However, in the Indian subcontinent, CF is less common. The exact incidence and prevalence figures are unknown. However, in European countries like the United Kingdom with significant number of immigrants from the Indian subcontinent, there are a substantial number of cystic fibrosis patients that are now being recognized.

The prevalence of CF in Asian immigrants in Britain has been estimated at around 1 in 10,000 and the clinical course tends to be more severe than matched non Asian controls.[31]

Genetics and Cellular Dysfunction

The CF mutation on chromosome 7 leads to an abnormality in a protein that is called Cystic Fibrosis Transmembrane Regulator (CFTR). This defective protein leads to the disruption of ion transport in epithelial lined organs, particularly the airways, but can also involve the sweat ducts, pancreatic ducts, bile ducts and the intestine. The genetic abnormality was isolated on chromosome 7.[32] This led to a great hope that gene therapy would eventually become a cure. Since 1989,over a 1,000 different mutations have been identified, any of which may produce the CF phenotype. Some of these mutations are extremely rare, however. The commonest mutation in the UK is deletion of phenylalanine (delta F508). A recent paper by Shastri et al. (2008) has described the commoner genetic mutations in India.[33]

Patients who are homozygous for delta F508 tend to have severe respiratory and pancreatic involvement although occasionally exceptions may occur. Indeed there is sometimes a discrepancy between the known genotype and the phenotype. There is increasing evidence of influence of other genes on different chromosomes, so called "modifying genes" and extensive research work is currently being carried out to identify such genes with potential implications for treatment. Potential modifying genes include mannose-binding lectin, transforming growth factor beta and protease inhibitors.

The CFTR is a 1,480 amino acid product coded for the long arm on chromosome 7. It is a glycoprotein and its function is to mediate ATP related chloride conductance. Deficiency of the CFTR causes reduced chloride conductance and consequent changes in sodium absorption by the cells. In the airways, excess sodium and water is absorbed across the cell membrane into the cell and this leads to a concentration of macromolecules and mucus in the airways. This, in turn, acts as a magnet for pathogens such as *Pseudomonas aeruginosa*. There is also some evidence that the defective CFTR may also be proinflammatory leading to airway damage in early childhood.

The CFTR mutations have been divided into five groups:

1. No synthesis, e.g. the nonsense mutation G542X
2. A block in processing, e.g. delta F508
3. A block in regulation, e.g. missense G551D
4. Altered conductance, e.g. missense R117H
5. Reduced synthesis, e.g. missense 455E.

Generally, groups 4 and 5 are associated with a mild phenotype. Some of these mild phenotypes may only present in adult life; in males they may be diagnosed first in the infertility clinics.

Diagnosis

Diagnosis is usually made in early childhood either by neonatal screening or by the development of symptoms such as failure to thrive or intestinal obstruction in neonates.

The diagnosis of cystic fibrosis depends upon a positive sweat test, gene analysis and also the clinical picture. Sweat testing classically involves pilocarpine iontophoresis, which is applied to the skin to stimulate sweat production, usually on the forearm. A 5 millivolt electric charge is then applied to the skin for 10 minutes and sweat is collected on a tiny piece of gauze. The chloride content of the gauze is then analyzed together with the difference in weights before and after sweat simulation. This then allows a sweat chloride level to be calculated. Normally, sweat chloride levels are less than 30 millimoles/liter. The diagnostic level for classical cystic fibrosis is a chloride level of 60 or more millimoles/liter. The sodium content will also be increased although usually not to quite such a high level as the sweat chloride level. If an abnormal sweat test is recorded it is usual to repeat the test to ensure accuracy. A small number of individuals will have a borderline sweat test between 30 and 59 millimoles/liter and this may be associated with the condition called "atypical cystic fibrosis." These tend to be patients, who have mild symptoms and who are often diagnosed in late childhood or as adults. Patients with atypical cystic fibrosis are less likely than classical CF patients to have pancreatic insufficiency.

Clinical Features

Cystic fibrosis is a multiorgan disease. The lungs bear the brunt of the disorder with eventual recurrent severe respiratory infections leading to bronchiectasis. However, 85% of CF patients have pancreatic insufficiency and around 5 to 10% have significant cystic fibrosis related liver disease. The liver disease occurs due to chronic inflammation of the bile ducts which may eventually lead to biliary cirrhosis. Many patients with CF have a low bone mass, partly due to the effects of chronic infection, but also partly due to the presence of the CFTR mutation itself. The sweat glands function abnormally and paradoxically produce a rise in sweat chloride and sodium levels, which is used (as detailed above) to diagnose the condition. Male patients are usually infertile due to inability of sperm to pass through the blocked vas deferens. With modern fertility treatments, sperms may be aspirated from the testes of such patients and *in vitro* fertilization may be possible. Generally, females with CF are fertile. Patients with CF are at increased risk of pneumothoraces (Fig. 60.4).

The CFTR abnormality leads to the development of thick and highly viscous sputum in the airways, which is very difficult for the patient to expectorate and also is an ideal area for bacterial colonization. The bacteria involved in respiratory infections in CF patients vary according to age. *Haemophilus influenzae* and *Staphylococcus aureus* are typical bacterial infections in earlier childhood. As the patient grows older, it is more likely that *Pseudomonas aeruginosa* will become the predominant pathogen and by late teens, over 50% of patients will be colonized with this organism. Chronic colonization may then lead to intermittent acute exacerbations leading to increasing shortness of breath and increased purulent sputum volume.

Infections and Treatment

The cornerstones of treatment are techniques to reduce the viscosity of sputum, improve airway clearance, treat lung infections vigorously and use anti-inflammatory agents. There is a considerable amount of research currently underway looking at the possibility of gene therapy and also drugs to influence ion transport.

An essential part of treatment is modifying and improving the nutrition of CF patients. Pancreatic insufficiency leads to poor fat absorption, which in turn, leads to abdominal symptoms of distension, diarrhea and malabsorption. Consequently, malnutrition leads to a stunting of growth and increased risk of severe lung infections.

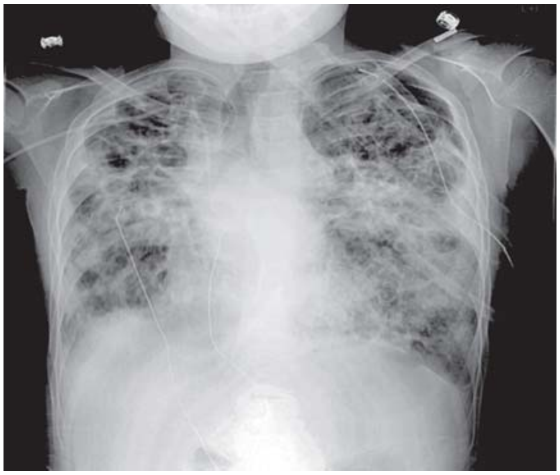

Fig. 60.4: Chest X-ray showing extensive bronchiectasis changes in a patient with cystic fibrosis. Intercostal tubes following a pneumothorax

In the early 1970s, a radical change in approach was made initially in Toronto, Canada, when a combination of high fat, high energy diets were used in combination with pancreatic enzyme supplements. Nowadays, this is the norm for managing such patients. This is extremely important because poor nutrition leads to an energy deficit with weight loss, poor respiratory muscle strength, increased pulmonary infection with increased lung damage and a vicious cycle of further lung infections.

Some patients with more advanced disease are helped by nasogastric feeding or feeding through a Percutaneous Endoscopic Gastrostomy (PEG) tube.

Other pathogens in cystic fibrosis, which are less common than *Pseudomonas aeruginosa* include the *Burkholderia cepacia* complex. These include around 14 different species or genovars. Genovars 2 and 3 are particularly infectious and damaging to the lung. Genovar 3 is called *B. cenocepacia* and this tends to be associated with the worst prognosis of patients infected with this complex. The Burkholderia complex is highly infectious and damaging to lung tissues and patients may deteriorate rapidly once they acquire this infection. Other gram-negative organisms, which may be isolated from the sputum include *Stenotrophomonas maltophilia*, Acinetobacter and Pandorea species. Some of these relatively rare gram-negative organisms may emerge due to the long-term effects of antibiotic pressure caused by the need for recurrent courses of intravenous antibiotics in CF patients. *Aspergillus fumigatus* may cause a direct necrotizing infection in the lungs, but more commonly some patients with CF may develop allergic bronchopulmonary aspergillosis.

An increasing problem in CF patients is the appearance of atypical nontuberculous mycobacteria especially Mycobacterium abscessus, but also occasionally *Mycobacterium avium-intracellulare* and *Mycobacterium kansasii*. These nontuberculous mycobacteria are usually extremely difficult to eradicate. The presence of such infection, particularly *Mycobacterium abscessus*, may be a relative contraindication to patients subsequently being accepted for lung transplantation.

CF patients have no detectable immune deficiency and bacteremia is uncommon. The altered airway secretions lead to increased sputum viscosity and then colonization with bacteria. There is a defect in the mucociliary escalator due to highly viscous sputum. Chronic infection causes collateral damage to lung tissue. The sputum itself consists of a large amount of bacterial DNA and phagocytic debris.

Exacerbations of lung infection in CF are diagnosed partly on a clinical basis in the terms of symptoms and signs, but also on evidence of a reduction in lung function particularly the FEV_1% predicted, sputum bacteriology sometimes, including bacterial counts and also X-ray or CT lung scan evidence.

Specific treatments of known bacterial infections in CF are as follows:

Staphylococcus aureus is usually treated with drugs such as flucloxacillin or fusidic acid. Some patients acquire MRSA and may require intravenous vancomycin, teicoplanin or oral/IV linezolid.

Haemophilus influenzae is often treated with co-amoxiclav.

Pseudomonas aeruginosa may be sensitive to oral ciprofloxacin and in some countries oral chloramphenicol is used (although there are concerns about its side effect of aplastic anemia). Often, *Pseudomonas aeruginosa* treatment requires intravenous antibiotics. The usual practice is to give at least two intravenous antibiotics together to reduce the risk of emergence of bacterial resistance.

High doses of intravenous antibiotics are often required in CF because of increased renal clearance of some antibiotics and also concerns about antibiotic penetration into the mucoid forms of *Pseudomonas aeruginosa* often with associated biofilms. Typical combinations for IV antibiotic use in CF include: Ceftazidime plus tobramycin or ceftazidime plus colomycin/colistin. Alternative to ceftazidime include meropenem, Tazocin or aztreonam.

If tobramycin or gentamicin is used, it is essential to check blood levels particularly the trough levels, to make sure that excessive doses are not leading to accumulation in the blood which may lead to toxicity to the inner ear and/or the kidneys.

Increasingly long-term nebulized antibiotics are used in CF patients who are colonized with *Pseudomonas aeruginosa*. The aim is to reduce the bacterial load in the lungs and delay tissue damage. Typical examples of nebulized antibiotics that are currently in use include tobramycin and colistin. Other nebulized forms of antibiotics are also currently being assessed, e.g. aztreonam, meropenem and ciprofloxacin.

Duration of IV antibiotic treatment is often around 14 days for pseudomonal infections. The dose and frequency of dosing with antibiotics depends partly on the type of antibiotic used. Some antibiotic effects are concentration dependent, i.e. the higher the peak blood level, the more effective it is, e.g. tobramycin. The idea here is to give high infrequent doses. Recently, single daily doses of tobramycin have become the norm rather than dosing two or three times per day. Other beneficial antibiotic effects depend upon the time above the minimum inhibitory concentration of that antibiotic for a particular bacterial infection. An example of this is ceftazidime. In this case, it is better to give frequent doses or even a continuous infusion rather than a single daily dose.

Lung function testing in CF usually occurs at each outpatient visit. Spirometry is the usual measurement made. As the disease progresses, the FEV_1% predicted progressively deteriorates. A decline in FVC is less rapid. It is important to recognize and to treat lung infections at an early age in children to try and delay airway colonization and to delay the rate of lung function decline with age.

The commonest way of now assessing pancreatic dysfunction is to measure fecal pancreatic elastase-1 levels in a small sample of feces rather than carrying out three or five day fecal fat collection. The more advanced the pancreatic disease, the lower the fecal 1 elastase level becomes.

Nutrition in CF usually aims for a high calorie, high fat diet often with additional food supplements. Sometimes, in addition, nasogastric or gastrostomy feeding is used. It is important to give oral fat soluble vitamin supplements to patients with CF related pancreatic deficiency, i.e. vitamins A, D, E and K.

Some older children and adults may develop abdominal distension and blockage due to Distal Intestinal Obstruction Syndrome (DIOS), previously called meconium ileus equivalent. Clinically, the patient complains of abdominal pain, bloating, vomiting or constipation. On examination, there may be a palpable lump in the right iliac fossa and a plain abdominal X-ray may show fecal loading and sometimes fluid levels. Treatment involves the use of bowel cleansing solutions.

CF related liver disease can lead in severe cases to biliary cirrhosis, which may then lead to portal hypertension. There are lung complications associated with severe liver diseases, including intrapulmonary shunting, pulmonary hypertension and respiratory muscle weakness due to poor nutrition. Also hepatomegaly may cause the right diaphragm to be raised and low blood albumin levels may lead to the onset of ascites and/or pleural effusions. Treatment includes the daily use of oral ursodeoxycholic acid. In severe cases, liver transplantation may be indicated.

The management of CF is based around a multidisciplinary team approach. The CF team consists of doctors, nurses, physiotherapists, dieticians and clinical psychologists with additional input from specialists in diabetes, liver disease, infertility, etc.

Chest physiotherapy is essential to help the patient clear the airways and there are a variety of physical maneuvers and mechanical devices, which aid sputum production. Nebulized bronchodilators are often used to help as well. Also many patients use a nebulized drug called DNase (dornase alfa), which is a drug that acts by cleaving bacterial DNA in the sputum, making it less viscous. The usual dose in adults is 2.5 mg nebulized once daily.

Other Treatments

There has been considerable interest in the development of anti-inflammatory drugs. Initially ibuprofen was used, but a significant number of patients suffered from side-effects from this medication. More recently, the macrolide antibiotic azithromycin has been used in a single daily dose of 250 mg in adults for its anti-inflammatory effects. Several studies have shown an improvement in lung function, quality of life and fewer infective exacerbations. Oral steroids may also have a beneficial effect in some patients, but of course this needs to be weighed against the problems of long-term side effects, particularly osteoporosis.

Cross infection between CF patients can be a serious problem. This was first recognized with *Burkholderia cepacia* infections, but more recently epidemic forms of *Pseudomonas aeruginosa* have been described and some of these epidemic forms may be more pathogenic than sporadic forms. Therefore, in outpatient clinics, both spacial and temporal separation of patients is required.

Lung transplantation should be considered when the patient's lung function has declined with an FEV_1% predicted of 30% or less.[34] When patients reach that level of lung function, the two year survival is around 50% and the potential advantages of lung transplantation should then be discussed with the patient.

Gene therapy is also being investigated in research trials at the moment. The main problem has been finding a suitable vector, which enables sufficient epithelial cells to become transfected with subsequent incorporation of the normal gene into the host's genome. Initial results appear very promising.

Prognosis

The median survival for cystic fibrosis has shown a remarkable improvement over the past few decades. For instance in the United States in 1985, the median survival was 25.5 years and in 2001, it was around 37 years. Generally, survival is better in patients who are pancreatic sufficient. Median survival is slightly better in males in comparison to female patients and is better in patients who have group 4 or group 5 CF mutations. There is also a close correlation between survival and poor nutritional status. Around 40% of adults with cystic fibrosis have CF-related diabetes. There is some evidence that raised airway glucose concentrations may increase the likelihood of frequent and more severe respiratory infections.

Finally, the story of the unraveling of the pathogenesis of cystic fibrosis and subsequent development of effective treatments has been one of medicine's great success stories during the past few decades. The management of the condition also serves as a model for multidisciplinary team working.

Rare Respiratory Infections

Mohankumar Thekkinkattil, S Arulmozhi

INTRODUCTION

There is an increased recognition of new and rare respiratory infections in clinical practice. These are attributed to the emergence of new pathogens especially in the immunocompromised patients.

VIRAL INFECTIONS

Several viruses complicate the course of Chronic Obstructive Pulmonary Disease (COPD), bronchial asthma and in patients in Intensive Respiratory Care Unit (IRCU). Immunosuppressed patients are susceptible to infections from cytomegalovirus, herpes viruses, adenoviruses and paramyxoviruses. Infections from hantaviruses, human metapneumoviruses, avian influenza A viruses and viruses of Severe Acute Respiratory Syndrome (SARS) and their mutations have been reported in the recent years. Upper respiratory tract infections due to viruses present with well-defined clinical syndromes according to the virulence and the dose of the viruses, and the resistance of the host.[1,2]

Human Metapneumovirus

Human Metapneumovirus (HMPV) is a human pathogen, which resembles Respiratory Syncytial Virus (RSV), causes respiratory illness in all age groups.[3-5] HMPV infection in children often exists with other respiratory virus infections especially the RSV. Maximum number of cases occurs during winter.[6,7] Clinical presentation varies from very mild to severe bronchiolitis and pneumonitis. The clinical features are often mistaken as RSV infection in children. It is common to have bronchiolitis, wheezing and severe hypoxemia, in children who are hospitalized. Nasal secretion levels of the virus chemokines RANTES are reported as suppressed whereas levels of IL8 are increased.[8]

Hantavirus Pulmonary Disease (HVPD)

Hantavirus pulmonary disease or Hantavirus hemorrhagic fever is an endemic zoonosis, which affects both adults and children in Europe and Asia. It has been also reported from India.[9] The causative agents belong to the genus hantavirus, of family Bunyaviridae.[9,10] It is carried by specific rodent host species, but host switches have been reported.[10,11] The clinical picture varies from place-to-place with the type of infection. Hemorrhagic complications like disseminated intravascular coagulopathy, severe thrombocytopenia, shock, oliguric renal failure, pleural effusion, ascites, neurological complications like hemiparesis, epilepsy and seizures are possible in this virus infection.[12-14] These infections are usually diagnosed by using IgM capture test and/or RT-PCR detection of viral RNA. Neutralization tests and gene sequencing are required for genotyping and serotyping. Immunofluorescence Immunoassay (IFA) or Enzyme-linked Immunosorbent Assay (ELISA) are also done in some cases.[15]

BACTERIAL INFECTIONS

Reye's-like syndrome associated with pertussis infection is generally seen in woman in coma with acute liver dysfunction, severe hypoglycemia and prolonged prothrombin time, may be mistaken for aspirin-induced Reye's syndrome.

Hemolytic-uremic syndrome in streptococcal pneumonia, is mainly seen in the young children, the morbidity and mortality are high. Pneumonia, disseminated intravascular coagulopathy, chronic renal and respiratory failure are important clinical features.[15] Lemierre's syndrome can rarely produce complications like septic arthritis, sternoclavicular joint sepsis and cavitating pneumonia.[16] The clinical features include fever, myalgia, tachypnea and tachycardia. Sometimes *Salmonella* can also involve the lungs.

Salmonella infections apart from the usual pneumonitis, can also produce myocarditis. Multiple organ failure in a previously healthy adult with or without fever, diarrhea, and shortness of breath, altered sensorium, acute pulmonary edema and respiratory failure should warrant a differential diagnosis of *Salmonella* infection. In some patients, hepatic and muscular enzymatic surge, rhabdomyolysis and disseminated intravascular coagulation have been reported.[17]

Streptococci in rare cases produce severe bacteremia and toxic shock syndrome in adults. High fever and tonsillopharyngitis, are often observed.

Community-acquired pneumonia by **Acinetobacter baumannii** is rare though an important example of nosocomial pneumonia. In subtropics, this is one of the causes of severe community-acquired pneumonia. The pathology consists of prominent cellular alveolar exudates with partial hyaline membrane and suppurative pneumonia.

RARE FORMS OF TUBERCULOUS INFECTIONS

Human tuberculosis typically caused by *Mycobacterium tuberculosis* complex, can rarely occur due to **rare genetic variants** such as *M. canettii*, *M. microti* and *M. pinnipedii*. The natural reservoir, mode of transmission and host factors are not well studied. So far, there is no drug resistance and the species are susceptible to rifampicin, pyrazinamide and ethambutol. Delayed growth on the solid media, contact with animals and special phenotypic pictures should be borne in mind for the diagnosis of these forms.[18]

Mycobacterium asiaticum was reported first in 1982. Chronic lung disease was a risk factor for pulmonary infection. It can produce both pulmonary and extrapulmonary disease. It responds well to standard anti-TB regimens.[19]

CHLAMYDIAL INFECTIONS

Chlamydia psittaci on intracellular gram-negative bacterium, which causes psittacosis has seven genotypes, A to F, which can be transmitted to humans from the bird's feces. The incidence seems to increase in the Western world . Clinical presentation varies from febrile episodes to the occurrence of severe pneumonia.[20] Pleuritic pain and dyspnea are common. Chest radiography shows ground-glass opacity with small areas of radiolucency. Hilar lymph nodes are involved in most of the cases.

Nocardia asteroides, an aerobic nonspore-forming bacterium can produce pulmonary nocardiosis. Clinical features include the presence of cough, increased sputum production, pleural pain and microabscesses. X-ray findings show air space consolidation and multilobar, nonsegmental nodules. True infection may involve the pleural space with effusions and empyema. The prognosis is good with treatment.[21]

Pulmonary actinomycosis is a relatively rare disease caused by *Actinomyces israelii*. Though they are gram-positive bacteria, the characteristic branching filaments clustered with neutrophils (sulfur granules) usually require special stain to diagnose. Coinfection with *S. aureus* increases the pathogenicity. It usually presents with pneumonia, mass-like consolidation will mimic malignancy. Airway obstruction is common.[22] Penicillin is the mainstay of treatment. Periodic therapeutic bronchoscopy may felicitate medical treatment.

Melioidosis (Whitmore's Disease)

Melioidosis is caused by *Burkholderia pseudomallei*, a bacterium. It is an infectious disease seen in humans, as well as in animals such as sheep, goats, horses, cattle, dogs and cats. Humans with underlying chronic illnesses through direct contact with the contaminated soil and water in endemic areas are more at risk of acquiring the infection. Pulmonary melioidosis may present as an acute or a chronic suppurative form. In acute pulmonary infection, the onset is associated with high-grade fever, headache, anorexia, chest pain, generalized myalgia, and productive cough with normal sputum production or with nonproductive cough. Patient may present with the symptoms of mild bronchitis to those of severe pneumonia. Lung abscess and empyema may also occur. Melioidosis is diagnosed from the blood, sputum or skin lesions by serology or by isolating *Burkholderia pseudomallei*. Radiological investigations like chest X-ray and CT thorax may show features of pneumonia. Treatment with antibacterials should be started as early as possible to prevent the progression. Drugs like penicillin, doxycycline, amoxicillin-clavulanic acid, imipenem, aztreonam or ceftriaxone are given intravenously for treatment.[23]

Tularemia (Rabbit Fever)

Francisella tularensis is a gram-negative facultative intracellular bacteria, which causes tularemia in animals. The organism that spreads by aerosol transmission, is highly virulent. Tularemia can be transmitted to humans by contact with infected animals or blood sucking arthropods like ticks, deer flies and mosquitoes. Pneumonic tularemia follows inhalation of *F. tularensis* during lawn mowing or bush cutting, which disturbs the carcasses and facilitate the release of bacterial aerosols. Patients present with cough, dyspnea, fever, chills, headache and pleurisy. Chest X-ray shows bronchopneumonia, hilar node enlargement with or without pleural effusion. Treatment with streptomycin or gentamicin subsides the symptoms.[24]

Rhodococcus equi

Formerly recognized as *Corynebacterium equi*, an opportunistic pathogen, causes pneumonia. It was commonly found in animals such as horses and cattle. In immunocompromised patients, R. equii causes pulmonary manifestations without any animal contact. In immunocompetent individuals, exposure to animals or soil contaminated with the animal waste is important to cause *Rhodococcus* disease. Patients usually present with the symptoms of pneumonia. Erythromycin, rifampicin and fluoroquinolones are recommended for treatment.

Moraxella catarrhalis

Moraxella catarrhalis was initially recognized as a commensal of pharynx. In recent years, it is shown to have significant pathogenicity in humans. *M. catarrhalis* requires iron for its growth in tissues. This organism utilizes hemoglobin as the source of iron.[25] Expression of type IV pillai, which in turn are affected by iron deficiency is required for natural persistent colonization of *M. catarrhalis* on mucosal surface.[26] The iron deficiency or inadequate heme component of hemoglobin is the vital factor for *M. catarrhalis* to become invasive.[27]

Meningococcal Pneumonia

Neisseria meningitidis colonizes the nasopharyngeal mucosa in 5 to 10% patients, but invasive disease is rare. Preceding viral respiratory infection facilitates the invasion. Patients present with fever, chills productive cough and pleuritic pain. Radiographic picture shows focal pneumonia. Rarely, *N. meningitidis* may cause interstitial pneumonitis, and the clinical picture resembles that of viral pneumonia. Histopathologically, the lung shows diffuse generalized, inflammation of the alveolar septa with intra-alveolar edema. The bacteremia results in lodging of the organisms and of meningococcal antigens in the interstitial capillaries of the lung. Diagnosis is made by immunohistochemical analysis and real time PCR assays. Antibiotics of penicillin group and cephalosporins are used for treatment. immunoprophylaxis is advisable for high-risk groups.[28-30]

PARASITIC INFECTION

Balantidium coli, a ciliated protozoan commonly causes intestinal infection. There are some rare cases of lung involvement. Thick-walled upper lobe cavity in a farmer with exposure to pig manure was reported with the disease. Bronchoalveolar lavage fluid showed trophozites of *B. coli*.[31] Doxycycline is the drug of choice.

Parasitic Pneumonias

Parasitic pneumonias are seen in many protozoan and helminthic infections. During the larval stage, the parasite passes through pulmonary circulation, gets sequestered resulting in pneumonia. Sometimes, pneumonia may result from direct extension from the contiguous sites. If left untreated, it may result in life threatening problems.[32] Due to the wide travel across continents and globalization, the parasitic diseases are now reported from all over the world, not only from the tropical and the subtropical regions. Parasitic pneumonias can be caused by protozoa, trematodes, cestodes and nematodes. *Leishmania donovani* causes pulmonary leishmaniasis in lung transplant patients and in other immunocompromised patients. *Entamoeba histolytica* infection results pulmonary amebiasis.

Tropical pulmonary eosinophilia present as chronic mild interstitial lung disease is caused by *Wuchereria bancrofti* and *Brugia malayi*.

Pulmonary dirofilariasis is caused by *Dirofilaria immitis* and *Dirofilaria repens*.

Pulmonary Malaria

Plasmodium falciparum, as well as *Plasmodium vivax* can cause pulmonary manifestations, in the severe forms of malaria. There is no typical malarial pneumonitis, and it may occur due to secondary bacterial or viral infections. The clinical symptoms consist of fever, cough and respiratory distress. Noncardiogenic pulmonary edema may sometimes occur. Diffuse interstitial edema, lobar consolidation, pulmonary edema and pleural effusion are important radiological findings. Treatment for severe malaria consists of injectable artemisinin, parenteral chloroquine, quinidine gluconate, and quinine hydrochloride. In severe respiratory distress conditions mechanical ventilation is recommended.[32]

ZOONOTIC BACTERIAL PNEUMONIAS

Yersinia enterocolitica of Enterobacteriaceae, commonly results in gastroenteritis. It can rarely cause pneumonias in immunocompromised individuals. Bacteremia causes spontaneous pleural empyema. Children are equally affected as adult. Treatment consists of third-generation cephalosporins, quinolones and chloramphenicol. Management of empyema may also require intercostal tube drainage and intrapleural fibrinolysis.[33-37]

Pasteurella multocida Infection

P. multocida may cause infection in humans following animal bite, scratch or lick, but may occur even without animal contact. Upper respiratory tracts are colonized by the *Pasteurella multocida* as commensals in cats and dogs, poultry, and domestic pet animals. *P. multocida* infection may occur in healthy, as well as immunocompromised persons. It affects all age groups, but more commonly in young children who have contact with pet animals. Elaborate history is needed to elicit exposure to animals. Skin manifestations, following animal bite mimic *Streptococcus pyogenes* infection. Pulmonary manifestations consist of sinusitis, otitis media, pharyngitis, mastoiditis, epiglottitis and Ludwig's angina. In cases with pre-existing chronic pulmonary disease, *P. multocida* may cause pneumonia, tracheo-bronchitis, lung abscess and empyema. Chronic obstructive pulmonary disease increases the mortality by 30%. The clinical presentation consists of hoarseness of voice, sinus tenderness and pharyngeal erythema. In addition to routine wound care for animal bite and vaccination prophylaxis, empirical antibiotic therapy is recommended for treatment. Oral antimicrobials like amoxicillin, amoxicillin-clavulanic acid combination, second-generation cephalosporins, carbapenems and fluoroquinolones are effective. In severe infections, parenteral antibiotics are recommended.[38-41]

Yersinia pestis

Yersinia pestis, a rod-shaped (safety pin appearance) facultative gram-negative anaerobe, can infect both humans and animals.[42] Commonly, rodents are the reservoir host for *Y. pestis*. In human plague outbreaks, fleas from other mammals may also have some role.[43] The vector, fleas acquires *Y. pestis* during feeding on an infected rodent.[44] Transmission of *Y. pestis* infection from rodents to humans occurs by skin contact. Human-to-human infection spreads by sneezing, coughing or through direct contact with the infected tissue. *Y. pestis* infection may clinically present in three forms: Bubonic plague, septicemic plague and pneumonic plague.

In pneumonic plague, the symptoms of the other two types are not always seen. Patients are present with various symptoms such as cough, dyspnea, fever, chills, chest pain, hemoptysis, hypotension, lethargy and shock. During severe bacteremia, several organs are affected resulting in disseminated intravascular coagulation and bleeding. Necrosis of skin and soft tissue, increases the mortality by over 20%. Early diagnosis of plague is difficult since the initial symptoms may mimic many other diseases.[45] Treatment is given with intravenous antibiotics for pneumonic plague. Streptomycin, gentamicin, chloramphenicol and fluoroquinolones are the first-line drugs used for the treatment.

In conclusion, the diagnosis of rare respiratory diseases requires taking a good clinical history, awareness of these diseases and appropriate diagnostic procedures. The list is not complete. The emergence of new pathogens, with modified lifecycles, newer genetic transformations, and mutations make rare infections a difficult proposition in the terms of diagnosis and treatment.

Parasitic Lung Diseases

VK Vijayan

INTRODUCTION

Lung diseases due to parasitic infections are common in tropical regions of the world.[1] However, these diseases are now being increasingly reported from many parts of the world due to globalization and travel across the continents.[2] The emergence of Human Immunodeficiency Virus (HIV) infection/Acquired Immunodeficiency Syndrome (AIDS), the frequent use of immunosuppressive drugs in many diseases and organ transplantations have also resulted in resurgence of parasitic lung infections.[3,4] Though many parasitic infections have a benign course, a large number of parasitic infections may cause considerable morbidity and mortality.[5] The important pulmonary diseases that can occur due to parasitic infections are listed in Table 62.1.

Pulmonary Amebiasis

Amebiasis is one of the most common infections in the world. It has been estimated that approximately 50 million cases of invasive amebiasis occur worldwide each year, with up to 100,000 deaths. Ingestion of mature *Entameba histolytica* cysts through fecal contaminated food, water or hands causes infection. The trophozoites released in the intestine pass through the bloodstream to reach extraintestinal sites, such as liver, and lungs resulting in pathological lesions. Pulmonary amebiasis occurs primarily due to extension of the amebic liver abscess.[6] The main manifestations of pleuropulmonary amebiasis are fever, right upper quadrant abdominal pain, chest pain and cough. Hemoptysis and expectoration of "anchovy sauce-like" pus indicates amebiasis.

The diagnostic findings in pleuropulmonary amebiasis are elevated hemidiaphragm, tender hepatomegaly, pleural effusion and basal pulmonary involvement. Active trophozoites of *E. histolytica* can be demonstrated in the sputum or pleural pus. Microscopic examination of stool samples may reveal cysts or trophozoites of amebae. The presence of ameba in the stool does not signify that the disease is due to *E. histolytica* as two nonpathogenic species found in humans (*E. dispar* and *E. moshkovskii*) are indistinguishable morphologically. Other diagnostic tests include culture of *E. histolytica* and serological tests [indirect hemagglutination test, Enzyme-linked Immunosorbent Assay (ELISA) and indirect fluorescent antibody test.]

Nitroimidazoles (metronidazole or tinidazole) are the main drugs used for the treatment of invasive amebiasis.[7] Metronidazole is given in a dose of 750 mg orally three times a day for 7 to 10 days. Tinidazole can be prescribed in a dose of 800 mg orally three times a day for 10 days. Treatment with nitroimidazole should be followed by treatment with a luminal amebicidal drug (paromomycin or diloxanide furoate) to cure intestinal luminal infection. Paromomycin is given as the total amount of 25 to 35 mg/kg per day in three divided doses for seven days or diloxanide furoate in a dosage of 500 mg orally three times a day for 10 days.

Pulmonary Leishmaniasis

The important protozoan parasites that cause leishmaniasis are *Leishmania donovani*, *Leishmania tropica*,

TABLE 62.1: Pulmonary diseases caused by parasitic infections

Diseases	*Parasites*
I. Protozoa	
1. Pulmonary amebiasis	*Entamoeba histolytica*
2. Pulmonary leishmaniasis	*Leishmania donovani*
3. Pulmonary malaria	*Plasmodium vivax*
	Plasmodium falciparum
	Plasmodium malariae
	Plasmodium ovale
	Plasmodium knowlesi
4. Pulmonary babesiosis	*Babesia microti*
	Babesia divergens
5. Pulmonary toxoplasmosis	*Toxoplasma gondii*
II. Helminths	
a) Cestodes	
1. Pulmonary cystic hydatidosis	*Echinococcus granulosus*
2. Pulmonary alveolar echinococcosis	*Echinococcus multilocularis*
b) Trematodes	
1. Pulmonary schistosomiasis	*Schistosoma haematobium*
	Schistosoma mansoni
	Schistosoma japonicum
2. Pulmonary paragonimiasis	*Paragonimus westermani*
c) Nematodes	
1. Pulmonary ascariasis	*Ascaris lumbricoides*
2. Pulmonary ancylostomiasis	*Ancylostoma duodenale*
	Necator americanus
	Ancylostoma ceylanicum
3. Pulmonary strongyloidiasis	*Strongyloides stercoralis*
4. Tropical pulmonary eosinophilia	*Wuchereria bancrofti*
(Filarial infection)	*Brugia malayi*
5. Pulmonary dirofilariasis	*Dirofilaria immitis*
	Dirofilaria repens
6. Visceral larva migrans	*Toxocara canis*
	Toxocara cati
7. Pulmonary trichinellosis	*Trichinella spiralis*

Source: Vijayan VK. Parasitic lung infections. Curr Opin Pulm Med 2009; 15(3):274-82.

Leishmania major and *Leishmania infantum*.[8] Various species of female *Phlebotomus* (the sand fly) transmits infection to man.[9] Leishmaniasis is endemic in Bangladesh, India, Nepal, Sudan and Brazil. It is seen predominantly in North Bihar, adjoining districts of West Bengal and eastern districts of Uttar Pradesh. Leishmaniasis and HIV infections often coexist in a deadly synergy and leishmaniasis accelerates the onset of AIDS in persons infected with HIV.[10] Visceral leishmaniasis is characterized by irregular fever, weight loss, enlargement of liver, and spleen and anemia. Pneumonitis, septal fibrosis, pleural effusion and mediastinal adenopathy are reported in patients coinfected with HIV. Leishmaniasis has also been reported in lung transplant patients.[11] *Leishmania* amastigotes can be found in the alveoli, pulmonary septa and Bronchoalveolar Lavage (BAL) fluid.

Diagnosis of leishmaniasis is by the demonstration of the parasites in bone marrow aspirates and by the demonstration of specific DNA sequences in tissues by molecular biology techniques. The treatment of leishmaniasis includes use of drugs such as amphotericin B, especially the liposome formulations and pentavalent antimonials.[12]. Liposomal amphotericin B is prescribed in a dosage of 3 mg/kg/day intravenously on days 1, 5, 15 and 21. Sodium stibogluconate is given in a dosage of

20 mg/kg daily intravenously or intramuscularly for 28 days.[8] Miltefosine, the first oral drug used for the treatment of visceral leishmaniasis is prescribed in a dosage of 2.5 mg/kg daily orally for 28 days and the maximum daily dose is 150 mg.[13] A single infusion of liposomal amphotericin B (in a dose of 10 mg/kg body weight) has been found to be as effective as conventional therapy with amphotericin B deoxycholate.[14]

Pulmonary Malaria

The malarial parasites that may infect humans are *Plasmodium vivax, P. falciparum, P. malariae, P. ovale and P. knowlesi* and are transmitted primarily by the bite of an infected female *Anopheles* mosquito. Falciparum malaria is the most deadly type of malaria infection.[15] The pulmonary manifestations range from cough to severe and rapidly fatal noncardiogenic pulmonary edema and Acute Respiratory Distress Syndrome (ARDS). Acute lung injury and ARDS have also been reported to occur in 3 to 30% of patients with severe malaria and has been described with falciparum, vivax and ovale malaria.[16,17] Acute lung injury and ARDS usually occur within a few days of onset of the disease, and even after initial response to antimalarial treatment and clearance of parasitemia. Pulmonary manifestations are common in children, pregnant women and travelers with malaria.[18] Pneumonia in malaria is also due to secondary bacterial infection. Pleural effusion is rarely reported in malaria. Light microscopy of stained thick and thin blood smears is the gold standard for the diagnosis of malaria. Thin smears allow identification of malaria species. Radiological findings in severe falciparum malaria include lobar consolidation, diffuse interstitial edema, pulmonary edema and pleural effusion. A polymerase chain reaction detection of *Plasmodium falciparum* in human urine and saliva samples has also been described.[19]

The drugs used for the treatment of severe malaria are quinine dihydrochloride, quinidine gluconate and injectable artemisinin derivatives. Artemisinin-based combination therapies (artesunate and sulfadoxine-pyrimethamine, artesunate and amodioquine, artesunate and mefloquine or artemether and lumefantrin) are amongst the best antimalarial drugs.[20] Quinine dihydrochloride is given Intravenously (IV) as a loading dose of 20 mg salt/kg body weight (bw) diluted in 10 ml/kg bw of 5% dextrose or dextrose saline over four hours. It is followed by the administration of maintenance dose of 10 mg/kg salt diluted in 10 ml/kg bw of 5% dextrose saline IV over four hours repeated every eight hours until the patient can swallow. Then quinine tablets are prescribed in a dose of 10 mg salt/kg bw every eight hours in combination with doxycycline or clindamycin to complete a seven-day-treatment course. Quinidine gluconate reconstituted in normal saline is infused IV in a dose of 10 mg/kg bw over one to two hours followed by a maintenance dose of 0.02 mg/kg per minute continuous infusion for at least 24 hours followed by oral medication. Artesunate is given as a loading dose of 2.4 mg/kg IV bolus at 0, 12 and 24 hours followed by the maintenance dose of 2.4 mg/kg daily for seven days. Artesunate is dispensed as a powder of artesunic acid and this is dissolved in 5% sodium bicarbonate to form sodium artesunate. The solution is then diluted in 5 ml of 5% dextrose which is given by IV injection. Once the patient can tolerate oral therapy, parenteral therapy is switched to a complete treatment course of an Artemisinin-Based Combination Therapy (ACT). Artemether is given as a loading dose of 3.2 mg/kg IM followed by the maintenance dose of 1.6 mg/kg IM daily.

The patients presenting with ARDS require invasive mechanical ventilation with intensive care management.[21] Early positive-pressure ventilation with lung protective strategy using low tidal volumes and appropriate Positive End Expiratory Pressure (PEEP) in volume assist control mode help to prevent the high mortality associated with ARDS in severe malaria.

Pulmonary Babesiosis

Babesiosis is caused by hemoprotozoan parasites, *Babesia microti* and *Babesia divergens.*[22] Man gets the infection by the bite of an infected tick, *Ixodes scapularis* and can also be infected from a contaminated blood transfusion. The parasite attacks the red blood cells and can be misdiagnosed as malaria. The risk factors for systemic infection are immunosuppression, advanced age and splenectomy. The symptoms are fever, drenching sweats, cough, tiredness, loss of appetite, myalgia and headache. Acute respiratory distress syndrome occurring a few days after initiation of medical therapy is an important pulmonary manifestation.[23] Chest radiological features include bilateral infiltrates with an alveolar pattern and thickening of the septa. Specific diagnosis is made by the examination of a Giemsa-stained thin blood smear, DNA amplification using PCR or detection of specific antibody. The peripheral blood smears may show, in addition to ring forms, tetrads inside the red blood cells. These tetrads known as Maltese cross formations are pathognomonic of babesiosis and are not seen in malaria.[24] Treatment is with a combination of clindamycin (600 mg every 6 hours) and quinine (650 mg every 8 hours) for 7–10 days or Atovaquone (750 mg every 12 hours) and azithromycin (500–600 mg on first day and 250–600 mg on subsequent days) for 7–10 days.[25]

Pulmonary Toxoplasmosis

Toxoplasmosis is caused by the protozoan parasite, *Toxoplasma gondii*. Cats are the primary carriers of the organism.[26] Human gets the infection by eating parasitic cystcontaminated raw or undercooked meat, vegetables or milk products. The symptoms of toxoplasmosis are flu-like syndrome, enlarged lymph nodes or myalgia. Pulmonary toxoplasmosis has been reported with increasing frequency in patients with HIV infection. Toxoplasma pneumonia can manifest as interstitial pneumonia/diffuse alveolar damage or necrotizing pneumonia. Diagnosis of toxoplasmosis is based on the detection of the protozoa in body tissues. A real-time PCR-based assay in BAL fluid has been reported in HIV-positive patients.[27,28] Toxoplasmosis can be treated with a combination of pyrimethamine (25–100 mg per day orally) and sulfadiazine (1–1.5 gram four times a day orally) for three to four weeks.[8]

TABLE 62.2: Rare pulmonary protozoal infections in immunocompromised individuals

Diseases	*Parasites*

Rare Pulmonary Protozoal Infections

Free living *Acanthameba* species can cause systemic disease with pulmonary manifestations of nodular infiltrates, pneumonitis and respiratory failure in immunocompromised patients.[29] *Cryptosporidium parvum* infection has been reported to produce interstitial pulmonary infiltrates and focal areas of consolidation in AIDS patients.[30] Recurrent aspiration secondary to mega esophagus can lead to pneumonitis, lung abscess and bronchieactasis in *Trypanosoma cruzi* infection (Chagas disease). Cardiogenic pulmonary edema and pulmonary hypertension secondary to cardiac failure and dilated cardiomyopathy have also been reported in Chagas disease.[31] East African trypanosomiasis due to *Trypanosoma brucei rhodesiense* has been reported to cause noncardiogenic pulmonary edema and ARDS in acute stage. Other rare pulmonary protozoal infections that have been reported in immunocompromised individuals are listed in Table 62.2.[8]

Pulmonary Cystic Hydatidosis

Cystic hydatidosis or hydatid cyst caused by *Echinococcus granulosus* is a serious health problem in most parts of the world particularly in sheep-raising areas of the Mediterranean countries, Middle East, the Balkan, South America, Australia and New Zealand. Dogs are the definitive hosts and sheep the main intermediate host. The liver is the primary location followed by the lungs.[32] Typically, the larvae that pass through or bypass the liver filter are trapped in pulmonary arterial capillaries. The entrapped larvae develop into hydatid cyst that grows gradually and often complicate by rupturing in the airway or less commonly in the pleural space. Secondary pulmonary hydatidosis may occur by rupture of a liver cyst in vena caval circulation or a heart cyst in the right ventricular cavity or primary lung cyst in the bronchi, and then seeding the protoscolices along the bronchial tree. In the majority of cases, primary lung hydatidosis is single. Multiple hydatidosis may be unilateral or bilateral. Patients are asymptomatic in the initial stages of infection. Chest pain, hemoptysis, dyspnea or allergic reaction may appear subsequently. Bronchial rupture of the cyst can result in the vomiting of contents of hydatid cysts. Intrapleural rupture may be acute leading to hydropneumothorax or empyema, or insidious with the delayed development of secondary pleural hydatidosis.

Secondary metastatic hydatidosis is often associated with the obstruction of pulmonary artery branches resulting in chronic hydatid cor pulmonale. Vomiting of small or entire hydatids is a specific sign called "hydatidoptysis."

Diagnosis of pulmonary hydatid cyst is still based on radiography and non-complicated cyst presents as well defined homogenous hydrous round ("cannon ball") opacity that may be lobulated by contiguous bronchovascular axes. Fissured or ruptured cyst in the bronchi may have the characteristic findings of "air crescent," pneumocyst, floating membrane, ring within a ring or completely empty cavity images. Thoracic ultrasonography may be useful if the cyst is accessible to ultrasound examination. It may confirm the cystic structure showing the characteristic double contour aspect (the pericyst and the parasite membrane endocyst) in non-ruptured cysts. Detached or retracted membrane may be observed in ruptured cysts. Daughter cysts are diagnostic in lung hydatidosis. Liver and abdomen ultrasound study is generally systematically performed to search for associated abdominal hydatid cysts. CT is helpful in doubtful cases, as it can analyze the internal structure of the cyst and measure the density; and evaluate the state of the neighboring parenchyma, the whole thorax and abdomen for associated cystic lesions or anomalies (Fig. 62.1).[2,33] Laboratory tests are complementary to clinical and imaging investigations. Eosinophils can be slightly increased in complicated cysts. Serological tests are less sensitive in patients with lung hydatidosis (65%) than in those where hydatid cysts are localized in liver (80% to 94%).[34]

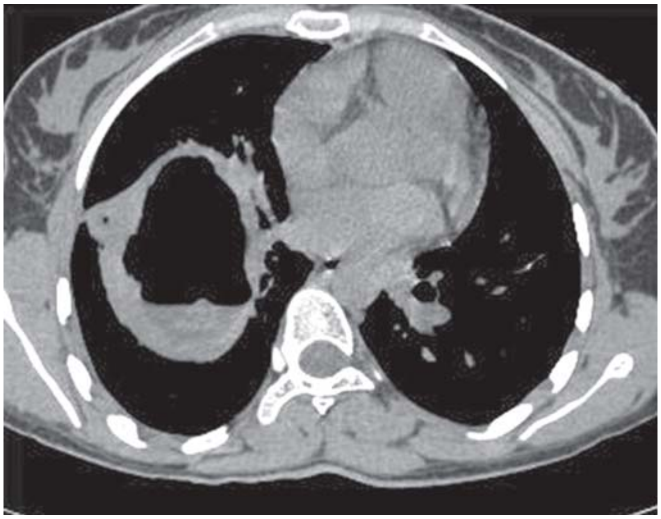

Fig. 62.1: Thoracic CT scan in a patient with cystic hydatid disease *(Source: Vijayan VK. Parasitic lung infections. Curr Opin Pulm Med 2009; 15(3):274-82).*

Surgery is the main treatment for pulmonary hydatidosis and aims to remove the parasite and treat associated parenchymal, bronchial or pleural disease. During surgery, spillage of hydatid fluid must be avoided to prevent secondary hydatidosis. Relapse rates up to 11.3% have been reported. Surgery must be as conservative as possible and resection is necessary in cases with severe and irremediable lung damage. Bilateral lung hydatidosis, present in 4 to 26% of operated cases, may be treated with one- or two-stage surgery either by bilateral thoracotomy or sternotomy. Video Assisted Thoracoscopic Surgical (VATS) approach can be safely used in selected cases with the same surgical rules as in open surgery.[35,36] Long-term treatment with benzimidazole carbamates (albendazole or mebendazole) has not been found to be very effective in lung hydatidosis. Treatment with benzimidazole has been suggested to prevent recurrences, though there is no evidence of their efficacy.[37,38] Treatment with these drugs has also been found to be associated with alopecia and hepatic and hematologic toxicity. Therefore, the medical therapy must be reserved for inoperable or complex cases. Percutaneous treatment by Puncture Aspiration Injection Reaspiration (PAIR) or percutaneous thermal ablation is used in hepatic hydatidosis. PAIR has been rarely used for lung hydatidosis because of the risk of anaphylactic shock, pneumothorax with pleural spillage and bronchopleural fistulae.

Pulmonary Alveolar Echinococcosis

Alveolar echinococcosis caused by *Echinococcus multilocularis* is a rare, but severe, highly pathogenic and potentially fatal form of echinococcosis. Wild canines especially the foxes are the definitive hosts and other hosts include dogs, cats and wolves. Small animals mainly rodents are the intermediate hosts. Alveolar echinococcosis is restricted to northern hemisphere (Europe, North America, some regions of China and Japan).[39] The liver is the first target of the parasite with a silent and long incubation period (5–15 years). Exogenous proliferation causes the infiltration of adjacent tissues and pressure necrosis. It can metastasize to distant organs mainly lungs, brain and bones. Lung involvement results from metastatic dissemination or direct extension through the diaphragm such as in case of hepatic echinococcosis with intrathoracic rupture into bronchial tree, pleural cavity or mediastinum. Direct extension to the right atrium through the inferior vena cava with recurrent episodes of pulmonary embolism has also been reported.

Imaging studies with radiography, ultrasonography, CT and Magnetic Resonance Imaging (MRI), may help in the diagnosis of metastatic lung disease. Biopsy may be needed to confirm the diagnosis.[40,41] Serologic tests, ELISA and Indirect Hemagglutination Assay (IHA) are available and are of great value for early detection in endemic areas to confirm diagnosis and to plan early surgery.[41] The radical resection of localized lesions is the only curative option for alveolar echinococcosis, but it is rarely possible in case of invasive and disseminated disease. Medical treatment is with mebendazole 40 to 50 mg/kg/day in three divided doses or with albendazole 10 to 15 mg/kg/day orally in two divided doses for a long period (minimum of two years) after radical surgery. Life-time treatment with medicines may be required for nonresectable or incompletely resected lesions.[38]

Pulmonary Schistosomiasis

The schistosomes that cause human disease are *Schistosoma haematobium*, *Schistosoma mansoni* and *Schistosoma japonicum*. The schistosome eggs are passed in urine (*S. haematobium*) or in feces (*S. mansoni* and *S. japonicum*) by the infected humans. The eggs released in fresh water are ingested by snails (intermediate host) in which the eggs hatch and develop into cercariae. The infective cercariae are excreted into the water and these cercariae penetrate human skin or are ingested to penetrate the gut. The final habitat of *S. haematobium* is urinary bladder vesicle beds and of *S. mansoni* and *S. japonicum* is the mesenteric beds. Pulmonary schistosomiasis can manifest clinically as an acute form and a chronic form. The acute form, also known as Katayama syndrome, present with fever, chills, weight loss, diarrhea, abdominal pain, myalgia, urticaria, shortness of breath, wheezing and dry cough and is seen in nonimmune patients.[42] Diffuse pulmonary infiltrates are seen radiologically in Katayama syndrome and almost all patients have eosinophilia.[43] Pulmonary nodules and pleural effusions have been reported in acute phase of infection with *Schistosoma mansoni*.[44]

Chest radiography and CT show small ill-defined nodular lesions, reticulonodular lesions or diffuse ground glass opacity. Chronic pulmonary schistosomiasis results from granulomatous reaction to eggs and/or worms embolized from pelvic veins in small pulmonary vessels through inferior vena cava for *S. haematobium*, or from mesenteric veins through portocaval anastomosis in patients with portal hypertension (*S. Mansonii* and *S. japonicum*).

Patients with chronic schistosomiasis present with the features of pulmonary hypertension and cor pulmonale.[45] Diagnosis of chronic schistosomiasis is based on the demonstration of eggs in stool or urine by direct microscopy or rectal/bladder biopsy.

Acute schistosomiasis can be treated with praziquantel 40 mg/kg for three days (for *S. mansoni* or *S. haematobium*) and 60 mg/kg for six days (for *S. japonicum*) with or without steroids.[8,43] Praziquantel can be repeated several weeks later to eradicate the adult flukes. Treatment may cause a reactive pneumonitis to dying eggs or worms. Acute pneumonia can be observed two weeks after treatment, which is thought to be related to lung embolization by detached adult worms in pelvic veins. Artemisinin has been found to be useful in the early stage after exposure, as the drug has been found to act on the juvenile forms of the schistosomes and may reduce the risk of the Katayama syndrome.[46] Chronic schistosomiasis can also be treated with praziquantel in the same dosage. Patients with pulmonary arterial hypertension are treated with specific pulmonary artery hypertension treatment along with antiparasitic medication.

Pulmonary Paragonimiasis

Ninety percent of the cases of paragonimiasis occur in Asia where nearly 20 million people are infected. Paragonimiasis is caused by infection with *Paragonimus* species and manifest as subacute or chronic inflammation of the lung. The main species that cause paragonimiasis in man is *Paragonimus westermani.* Adult worms live in the lungs and the unembryonated eggs of *P. westermani* are excreted in the sputum, or they can be swallowed and passed with stool. The eggs become embryonated in the external environment and miracidia are produced. The miracidia penetrates the soft tissues of the first intermediate host, a snail and go through several developmental stages inside the snail forming free swimming cercariae. Many cercariae then emerge from the snail and invade the second intermediate host, a crustacean such as a crab or crayfish. Cercariae encyst and produce metacercariae, which are the infective stage for the mammalian host. Man gets the infection, when raw or undercooked crabs or crayfishes contaminated with infective metacercariae are ingested. The metacercariae excyst in the duodenum, penetrate through the intestinal wall into the peritoneal cavity, then through the abdominal wall and diaphragm into the lungs. In the lungs they become encapsulated and develop into adults.

Pulmonary manifestations include fever, chest pain, chronic cough with blood tinged sputum or hemoptysis that may mimic tuberculosis. Pleural effusion or pneumothorax may be the first manifestation during intrapleural migration of the juvenile worms.[47,48] Chest radiography or CT may show patchy airspace consolidation due to exudative or hemorrhagic pneumonia that may cavitate. Worm cysts may be seen as solitary or multiple nodules or gas filled cysts with ring shadows and crescent-shaped areas within the cyst that represent worms attached to the wall of the cavity.[49,50]. Diagnosis is confirmed by the detection of eggs in the sputum samples, BAL fluid or lung biopsy specimens. Fine Needle Aspiration Biopsy (FNAB) of pulmonary nodule has been found to be useful in the diagnosis of pulmonary paragonimiasis.[51] Peripheral blood eosinophilia and elevated serum IgE levels are seen in more than 80% of patients with paragonimiasis. Differentiation of paragonimiasis from tuberculosis may be difficult. Paragonimiasis can be treated with praziquantel (75 mg/kg/day for 3 days), bithionol (30–40 mg/kg for 10 days, every alternate day), niclofolan (2 mg/kg as a single dose) or triclabendazole (20 mg/kg in two equal doses).

Pulmonary Ascariasis

Ascaris lumbricoides is the most common intestinal helminthic infection. The fertilized eggs passed in the feces and released in the soil embryonate within two to four weeks and become infectious depending on the environmental conditions (moist, warm and shaded soil). Infection occurs through the contamination of hands or food with soil containing eggs, which is then swallowed. The eggs hatch into larvae in the small intestine. These first stage larvae moult into second stage larvae in the lumen of the small intestine. The second stage larvae penetrate the wall of the intestine and travel via capillaries and lymphatics to the hepatic circulation and to the right side of the heart and then reach the lungs. The second stage larvae moult twice more in the alveoli to produce third and fourth stage larvae. The fourth stage larvae are formed 14 days after ingestion, travel up to the trachea and are then swallowed to reach back the small intestine.

Respiratory symptoms are due to larval pulmonary migration, airway hyper reactivity and bronchospasm. Symptomatic pulmonary disease may range from mild cough to Löffler's Syndrome.[52] Löffler's Syndrome is a self-limiting inflammation of the lungs and is associated with blood and lung eosinophilia. This syndrome can occur as a result of parasitic infestation (especially ascariasis in children) and exposure to various drugs. Patients may present with the general symptoms of malaise, loss of appetite, fever lasting two to three days, headache and myalgia. The respiratory symptoms include chest pain, cough with mucoid sputum, hemoptysis, shortness of breath and wheezing. The respiratory rate may increase and rales can be heard on auscultation. Leukocytosis, particularly eosinophilia is an important laboratory finding. Chest radiographs demonstrate unilateral or bilateral, transient, migratory, or nonsegmental opacities of various sizes. These opacities are often peripherally situated and appear to be pleural based.

A diagnosis of pulmonary disease due to ascariasis can be made in an endemic region in a patient who presents with dyspnea, dry cough, fever and eosinophilia. Sputum may show Charcot-Leyden crystals and the chest radiograph may reveal fleeting pulmonary infiltrates. Due to the occurrence of respiratory symptoms during larval pulmonary migration, stool examination usually does not show *Ascaris* eggs and stool samples may be negative until two to three months after the occurrence of respiratory symptoms, unless the patient had been previously infected. Larvae can sometimes be demonstrated in respiratory or gastric secretions.

Pulmonary disease due to ascariasis usually does not require any treatment, as it is a self-limiting disease. However, the persistence of gastrointestinal ascariasis may result in repeated episodes of respiratory symptoms due to larval migration. In order to eradicate *Ascaris lumbricoides* from the intestine, specific anthelminic treatment is given. Mebendazole and albendazole are equally effective in the treatment of ascariasis.[53] Mebendazole is given in a dose of 100 mg twice a day for three days. It can be also given as a single dose of 500 mg. Albendazole is given as a single dose of 400 mg. The safety of mebendazole and albendazole during pregnancy has not been established. A single dose of pyrantel pamoate (11 mg/kg, maximum dose 1 gram) and piperazine citrate (50 to 75 mg/kg/day for 2 days) are also useful in the treatment. Pediatric dose is same as adult dose. Ivermectin has also been found to be useful.[54]

Pulmonary Ancylostomiasis

Ancylostomiasis or "hookworm disease" is caused by three parasite species, *Ancylostoma duodenale, Necator americanus* and *Ancylostoma ceylanicum*. Man is the only definitive host. The eggs containing segmented ova with four blastomeres are passed out in the feces. A rhabditiform larva develops from each egg in the soil and this larva moults twice and develops into a filariform larva, which is infective to man. The filariform larva penetrates through the intact skin. *N. americanus* larvae can infect man only through the skin whereas *A. duodenale* larvae can enter the human host via the oral route in addition to the entry through the skin.[55] These larvae reach pulmonary circulation through the lymphatics and venules. The larvae then pierce the alveolar walls and ascend the bronchi, trachea, larynx and pharynx and are ultimately swallowed to reach the upper part of small intestine. The interval between the time of skin penetration and laying of eggs by adult worms is about six weeks.

Ancylostoma dermatitis which manifests in form of intense pruritus, erythema and rash (ground itch) occurs at the site of skin penetration. During pulmonary larval migration, patients may present with fever, cough, wheezing and transient pulmonary infiltrates in chest radiographs. This is associated with blood and pulmonary eosinophilia. The other characteristic feature is iron-deficiency anemia due to chronic blood loss. During massive infection from oral ingestion of hookworm larvae, patients can present with nausea, vomiting, cough, dyspnea and eosinophilia. This condition is termed as Wakana disease. Prominent gastrointestinal symptoms in hookworm disease are abdominal pain, nausea, anorexia and diarrhea.

A direct microscopical examination of stool demonstrates the presence of characteristic hookworm eggs. Concentration method may be used when the infection is light. Eosinophilia in the peripheral blood is a prominent finding. A peripheral blood smear examination will reveal microcytic hypochromic anemia. A Polymerase Chain Reaction (PCR) to differentiate between *À. duodenale* and *N. americanus* has been developed.[56] Both mebendazole and albendazole are useful in the treatment of hookworm infestation. Mebendazole is given as 100 mg twice daily for three days and albendazole is given as a single dose of 400 mg. Pyrantel pamoate at a dose of 11mg/kg orally (maximum 1g) as a single dose has also been found to be useful. Ivermectin can also be used in the treatment of hookworm infections. Anemia can be treated with oral ferrous sulfate tablets.

Pulmonary Strongyloidiasis

Strongyloides stercoralis is seen worldwide, but is common in South America, South East Asia, sub-Saharan Africa and the Appalachian region of the United States of America. The parasitic females live in the wall (mucous membrane) of the small intestine of human and lays eggs. The rhabditiform larvae emanating from the eggs pierce the mucous membrane and reach the lumen of the intestine. These larvae are then passed with the feces and eggs are, therefore, not found in the feces. The rhabditiform larvae can metamorphose into filariform larvae in the lumen of the bowel. These filariform larvae can penetrate the intestinal epithelium or perianal skin without leaving the host. This is responsible for autoinfection and for the persistence of infection for 20 to 30 years in persons who have left the endemic areas.[57]

The unique feature of the life cycle of *S. stercoralis* is that it can complete its life cycle either in the human host or in the soil. The rhabditiform larvae that are voided with the feces can undergo two distinct cycles in the soil: Direct (host-soil-host) and indirect cycle. In direct cycle, the rhabditiform larvae directly metamorphose into filariform larvae and can infect human through skin. In indirect cycle, the rhabditiform larvae mature into free-living sexual forms (males and females). A second generation of rhabditiform larvae is then produced and these are subsequently transformed into filariform larvae. The filariform larvae can penetrate directly through the skin, invade the tissues, penetrate into the venous or lymphatic channels and are carried by the blood stream to the heart and then to the lungs. They pierce the pulmonary capillaries and enter the alveoli. These larvae, then, migrate to the bronchi, trachea, larynx and epiglottis and are swallowed back into the intestine. In the duodenum and jejunum, they develop into sexual forms to continue their life cycle.

The cutaneous reaction, as a result of the penetration of the skin by the filariform larvae may be due to immediate hypersensitivity reaction. The cell mediated immunity that develops following primary infection prevents reinfection.[58]. As a result, the larvae and adult worms remain confined to the intestine and the tissue invasion is prevented in immunocompetent individuals. When there is immunosuppression, autoinfection is exaggerated and leads to hyper infection. In this situation, the number of migrating larvae increases tremendously and disseminate into many organs, including lungs, meninges, brain, lymph nodes and kidneys. The parasite can produce hyperinfection syndrome in individuals with deficient cell-mediated immunity as seen in patients with immunosuppressive therapy (especially corticosteroids) and other immune-deficient states (malnutrition, lymphoma, leukemia, etc.). HIV-infected patients are at a higher risk of dissemination and this may occur without the elevations of IgE or eosinophils.[59]

During the migration of filariform larvae through the lungs, bronchopneumonia and hemorrhages in the alveoli can occur. These areas are infiltrated with eosinophils. This is associated with elevated IgE levels and eosinophilia in the blood. As the larvae penetrate the intestinal mucosa, gram-negative bacteria from the gut are carried by the larvae on their cuticle. In addition, small breaks in the mucous membrane as the larvae penetrate the intestine also facilitate the entry of enteric bacteria into the blood stream. The inflammation that follows such invasion of larvae leads to disseminated strongyloidiasis and this is usually fatal. As a result of invasion of bacteria along with larvae, diffuse and patchy bronchopneumonia and pulmonary abscess can occur. In the lung, massive pulmonary bleeding can occur due to alveolar microhemorrhages.

Pulmonary signs and symptoms include cough, shortness of breath, wheezing and hemoptysis.[60] In patients at high risk for strongyloidiasis, acute respiratory distress syndrome and septicemia due to intestinal transmural migration of bacteria can occur. In addition, acute anemia, acute renal failure and systemic inflammatory response syndrome have been reported.[61]. In immunocompetent patients with strongyloidiasis, the parasite load is usually low and the larval output is irregular. As a result, the diagnosis of strongyloidiasis by the examination of a single stool specimen using conventional techniques usually fails to detect larvae in up to 70% of cases. The diagnostic yield can be increased by examination of several stool specimens on consecutive days. In disseminated disease, larvae and adult parasites can be seen in sputum, urine, bronchoalveolar lavage fluid and other body fluids.

Ivermectin, thiabendazole or albendazole can be used for treatment of strongyloidiasis in immunocompetent individuals without complications. Ivermectin is given in a dose of 200 µg/kg orally for one or two days. Thiabendazole is given orally as 25 mg/kg twice a day for two days. Albendazole 400 mg twice a day for five days has been found to be useful in the treatment of strongyloidiasis. In immunocompromised individuals with disseminated strongyloidiasis, the dose of thiabendazole has to be doubled and the duration of treatment may extend up to several weeks. Corticosteroids should not be prescribed to prevent life-threatening hyperinfection syndrome.

Tropical Pulmonary Eosinophilia

Immunologic hyper responsiveness to human filarial parasites, *Wuchereria bancrofti* and *Brugia malayi* results in an occult form of filariasis termed as Tropical Pulmonary Eosinophilia (TPE).[62] The evidences for filarial etiology of TPE are the close epidemiological relationship between filarial infection and TPE, a positive filarial complement-fixation test and a positive immediate reaction to intradermal skin tests with *Dirofilaria immitis* antigens, histopathological demonstration of microfilariae of *Wuchereria bancrofti* in the lungs, liver and lymph nodes of patients, the usefulness of Diethylcarbamazine Citrate (DEC), an antifilarial drug, in the treatment, elevated levels of filarial specific IgG and IgE antibodies and the ultrasonographic demonstration of living adult *Wuchereria bancrofti* in the lymphatic vessels of the spermatic cord of patients with TPE.

The demonstration that basophils from patients with TPE released greater amounts of histamine when cells were challenged with *Brugia* or *Wuchereria* antigens than with *Dirofilaria* antigen suggested that TPE resulted from immunologic hyper responsiveness to human filarial parasites.[63-68] Histopathological examination of lung biopsy specimens has shown acute eosinophilic infiltrations of interstitial, peribronchial and perivascular tissues leading to the formation of eosinophilic abscesses and eosinophilic bronchopneumonia in the acute stage and in untreated cases, fibrosing alveolitis with honey combing.[63]

Bronchoalveolar lavage studies have demonstrated that TPE is characterized by intense eosinophilic inflammatory process in the lower respiratory tract.[69] Electron microscopic examination of lung eosinophils had shown severe degranulation with the loss of both the cores and the peripheral portions of the granules, suggesting that the eosinophils were in an activated state.[68,69] A major IgE-inducing antigen (Bm23-25) of the filarial parasite, *Brugia malayi* has been identified and this antigen has been found to be the homolog of the enzyme, gamma-glutaryl transpeptidase light chain subunit [66,70] and expresses mainly in the infective L3 larvae.[71] In addition, *Brugia malayi* gamma-glutaryl transpeptidase can induce IgG1 and IgE antibody production in patients with TPE.[72] BAL fluid from patients with TPE contains IgE antibodies that recognize *Brugia malayi* antigen, Bm23-25.[66] There is a molecular mimicry between the parasite gamma-glutaryl transpeptidase and the human gamma-glutaryl transpeptidase present on the surface of pulmonary epithelium. Thus, the profound antibody response to filarial infection especially to filarial gamma-glutaryl transpeptidase, observed in the lungs of patients with TPE, plays an important role in the pathogenesis of tropical eosinophilia.

Tropical pulmonary eosinophilia is prevalent in India, Pakistan, Bangladesh, Sri Lanka, Myanmar, Malaysia, Singapore, Indonesia and Vietnam. Tropical pulmonary eosinophilia is a systemic disease involving mainly the lungs, but other organs, such as liver, spleen, lymph nodes, brain, GIT, etc., may also be involved. The disease occurs predominantly in males, with a male to female ratio of 4:1, and is mainly seen in older children and young adults between the ages 15–40 years.[63] The systemic symptoms are fever, weight loss and fatigue. Respiratory symptoms include paroxysmal cough, breathlessness, wheeze and chest pain. The symptoms occur predominantly at night, but can persist during the day. Sputum is usually scanty, viscous and mucoid. The sputum often shows clumps of eosinophils; and rarely Charcot-Leyden crystals. On examination, patients are often breathless. Bilateral scattered rhonchi and rales may be also heard on auscultation.

Leukocytosis with an absolute increase in eosinophils in the peripheral blood is the hallmark of TPE. Absolute eosinophil counts are usually more than 3,000 cells/mm^3 and may range from 5,000 to 80,000.[73] As patients with TPE especially from endemic areas can be simultaneously infected with other helminthic parasites, stool examination may reveal ova or larvae of other helminths (*Ascaris*, *Ancylostoma*, whipworm, and *Strongyloides*) in 20% of patients with TPE. This observation does not deter the physician from making a diagnosis of TPE, if other conditions for diagnosis are fulfilled.

The chest radiological features of TPE include reticulonodular shadows predominantly seen in mid and lower zones and miliary mottling of 1–3 mm in diameter often indistinguishable from miliary tuberculosis. Twenty percent of patients have a normal chest radiograph.[63] Lung function tests reveal mainly a restrictive ventilation defect with superimposed airway obstruction.[74,75] Single breath carbon monoxide transfer factor (TLCO) is reduced in 88% of untreated patients with TPE.[76] The reduction in TLCO is due to reduced pulmonary membrane diffusing capacity (Dm).[77] Most of the patients exhibit mild arterial hypoxemia. Following three weeks treatment with DEC, pulmonary function parameters, including TLCO continued to be significantly lower than the control subjects.[74]

Until a diagnostic test that can differentiate filarial TPE from other TPE-like syndrome due to other helminthic infections is available, the following diagnostic criteria can be used for the diagnosis of TPE:

(a) Appropriate exposure history (mosquito bite) in an endemic area of filariasis,
(b) A history of paroxysmal nocturnal cough and breathlessness,
(c) Chest radiographic evidence of pulmonary infiltrations,
(d) Leukocytosis in blood,
(e) Peripheral blood eosinophils more than 3,000 cells per cu mm,
(f) Elevated serum IgE levels,
(g) Elevated serum antifilarial antibodies (IgG and/or IgE) and
(h) A clinical response to diethylcarbamazine citrate.

The treatment is with oral DEC (6 mg/kg per day) for three weeks.[78] Relapses following treatment occur in approximately 20% of patients followed up for five years.[63] Though most patients show marked symptomatic improvement, there is an incomplete reversal of clinical, hematological, radiological and physiological changes in TPE one month after a three-week course of DEC.[74,79]. Thus, a chronic mild interstitial lung disease has been found to persist in TPE despite treatment.[80]

Pulmonary Dirofilariasis

Pulmonary dirofilariasis is a zoonotic infection caused by filarial nematodes, *Dirofilaria immitis* and *Dirofilaria repens*. Humans are accidental hosts of this parasite, which is transmitted by the mosquito. The parasite, which is a vascular parasite[81] is usually seen in the pulmonary artery where they produce a pulmonary nodule or "coin lesion."[82] Nearly 50% of subjects infected with dirofilariasis are asymptomatic. Clinical symptoms are chest pain, cough, fever, hemoptysis and dyspnea. CT scan may show a well-defined nodule with smooth margin connected to an arterial branch.[83] Rarely cavity formation in the lung has also been reported. A PCR-based diagnosis of *D. repens* in human pulmonary dirofilariasis is available. A definitive histopathological diagnosis of pulmonary dirofilariasis can be made in tissue specimens obtained by wedge biopsy, video-assisted thoracoscopy or rarely by fine needle biopsy. There is no specific treatment for human dirofilariasis.

Pulmonary Visceral Larva Migrans

Certain nematode parasites when enter into an unnatural host (e.g. human) may not be able to complete their life cycle and their progress is arrested in the "unnatural host." If the entry of such parasitic larvae is through skin penetration, it causes cutaneous larva migrans (creeping eruption). If the entry is via oral route, it causes visceral larva migrans. Cutaneous larva migrans is caused by the parasite, *Ancylostoma braziliense*, which is a parasite of dogs and cats. The common parasites that cause Visceral Larva Migrans (VLM) and eosinophilic lung disease in human are a dog ascarid *(Toxocara canis)* and less commonly a cat ascarid (*Toxocara catis*). Adult *Toxocara canis* and *Toxocara catis* live in the intestines of dogs and cats respectively.

Animals acquire infection by the ingestion of eggs of the parasites from contaminated soil. The life cycle is then completed in definitive hosts, dogs and cats and the eggs are passed by the animals in the feces and embryonate in the soil. These embryonated *Toxocara* eggs, when ingested by an intermediate host (e.g. human), hatch into infective larvae in the intestine. The infective larvae penetrate the intestinal wall and are carried by the circulation to many organs, including liver, lungs, muscles, central nervous system and eye. The progress of the larvae is arrested in these sites of the intermediate host by the formation of a granulomatous lesion. In human, the larvae never develop into adult worms. Therefore, infected human never excretes *Toxocara* eggs in the feces. The larvae can get encapsulated within the granuloma where they are either destroyed or persist for many years in a viable state. Larval antigens can cross-react with human A and B blood group antigens.[84]

The main symptoms in patients with VLM are fever, cough, wheezing, seizures, anemia and fatigue. Pulmonary manifestations are reported in 80% of cases and patients may present with severe asthma. Scattered rales and rhonchi are heard on auscultation. Visceral larva migrans is characterized by leukocytosis and eosinophilia. Skiagram chest may reveal focal patchy infiltrates. In some cases, severe eosinophilic pneumonia may lead to respiratory distress.[85] Other clinical features include generalized lymph node enlargement, hepatomegaly and splenomegaly. Visceral larva migrans is usually reported in young children with a history of pica. A history of exposure to puppies or dogs supports the diagnosis of VLM. Serological tests by ELISA method using excretory-secretory proteins obtained from cultured *T. canis* may be useful in the diagnosis. Histopathological examination of lung or liver biopsy specimens may demonstrate granulomas with eosinophils, multinucleated giant cells and fibrosis. Since man is not the definitive host of *Toxocara* species, eggs or larvae cannot be demonstrated in the feces.

Visceral larva migrans is a self-limiting disease and there may be spontaneous resolution. Therefore, mild to moderately symptomatic patients need not require any drug therapy. Patients with severe VLM can be treated with thiabendazole, mebendazole or DEC. Treatment with antihelmintics may exacerbate the inflammatory reactions in the tissues due to the killing of larvae. It is therefore, advisable to combine antihelmintic treatment with corticosteroids. Diethylcarbamazine citrate can be given in a dose of 6 mg/kg/day for 21 days. Mebendazole is prescribed in a dose of 20–25 mg/kg/day for 21 days.[86] Albendazole 10 mg/kg/day for five days has been shown to have a moderate effect compared to thiabendazole.

Pulmonary Trichinellosis

Human trichinellosis is an important food-borne zoonosis. Five species of *Trichinella* (*T. spiralis*, *T. nativa*, *T. nelsoni*, *T. britovi* and *T. pseudospiralis*) can infect human.[87] The most important species that infect human is *Trichinella spiralis*. The parasite has a direct life cycle with complete development is one host (pig, rat or human). However, two hosts are required to complete the life cycle and for the preservation of the species from extinction. Human gets infection from raw and partially cooked pork, when infected pig's muscle containing the larval form of trichinellae is eaten by human. The infective larvae in the muscle are surrounded by a host capsule, which is a modified striated muscle known as "nurse" cell. In the stomach, the "nurse" cell is digested and the free larva is liberated. The larvae develop into adults (males and females) in the duodenum and jejunum. The newborn larvae produced by female parasites pass through the lymphatics or blood vessels to reach the striated muscles.[88] The larvae undergo encystment in the muscle and a host capsule develops around the larvae. Later on, it may get calcified. The life cycle is completed when infected muscle is ingested by a suitable host.

The common symptoms of trichinellosis are muscle pain, periorbital edema, fever and diarrhea.[89] Pulmonary symptoms include dyspnea, cough and pulmonary infiltrates. Dyspnea may be due to the involvement of diaphragm. Leukocytosis , eosinophilia and elevated levels of serum muscle enzymes (creatine phosphokinase, lactate dehydrogenase, aldolase and aminotransferase) are important laboratory findings. An enzyme-linked immunosorbent assay for the detection of anti-*Trichinella* antibodies using excretory-secretory antigens may be useful in the diagnosis. A definitive diagnosis can be made by muscle biopsy (usually deltoid muscle) that may demonstrate larvae of *T. spiralis*.[90]

Symptomatic treatment of trichinellosis includes analgesics and corticosteroids. Specific treatment is with mebendazole 200 to 400 mg three times a day for three days followed by 400 to 500 mg three times a day for 10 days. Albendazole can be given in a dosage of 400 mg per day for 3 days followed by 800 mg per day for 15 days. Trichinellosis can be prevented by consuming properly cooked pork.

Anaerobic Bacterial Infections of the Lungs and the Pleura

Ashok Shah, Chandramani Panjabi

INTRODUCTION

The role of anaerobes in causing an infective disease process has been appreciated for more than a century, but anaerobic bacterial infections of the respiratory system continue to remain in the subconscious domain of the pulmonologist. Anaerobes as the cause of respiratory infection are infrequently recognized and rarely established. More often than not, these infections are caused by endogenous organisms that predominantly are commensals of the upper respiratory tract. Disruption of the harmonious relationship between the host and the bacteria lead to the various clinicopathologic processes that occur with anaerobic pleuropulmonary infections (Table 63.1).

TABLE 63.1: Clinical categories of anaerobic pleuropulmonary infections

1. Acute pneumonia (consolidation)
   - i. Aspiration pneumonia
   - ii. Community acquired pneumonia
   - iii. Nosocomial pneumonia
2. Chronic anaerobic pneumonitis (pulmonary infiltrates without cavitations)
3. Lung abscess (usually single, greater than 2 cm)
4. Necrotizing pneumonia (bilateral lung infiltrates with multiple cavitations less than 1 cm)
5. Pleural empyema
6. Septic emboli

HISTORICAL NOTE

In 1860, Antonie van Leeuwenhoek, the inventor of the microscope, discovered some "animalcules," which survived in the absence of air.[1] After almost two centuries, Louis Pasteur coined the term "anaerobies" and recognized the phenomenon of anaerobiosis.[2] A few years later, Veillon identified anaerobic cocci in four patients.[3] Anaerobic pleuropulmonary infections were first described in detail a little more than a century ago by Rendu and Rist in 1899.[4] A few years later, Guillemont and coworkers[5] published 13 cases of putrid "empyema". Subsequently, during the next two decades, infections caused by the synergy of fusiform bacilli and spirochaetes were documented.[6-8] These "fusospirochaetal" bacteria were first described by Willoughby Miller, a dentist, in 1883;[9] while ulcerative gingivitis due to these bacilli was reported in detail by Vincent.[10] These microbes, popularly known as "Miller-Vincent" organisms, were chiefly responsible for pulmonary spirochaetosis.

During the late 1920s, elegant work done by Dr David Smith[11] on lung abscess revealed the resemblance of the bacteria seen in the walls of abscesses, on autopsy, to the organisms present in the gingival crevice of healthy individuals. This led to the postulation that lung abscesses commonly occurred due to the aspiration of oral microbial flora. Experimental animal studies[12-14] to prove this hypothesis demonstrated that four anaerobic bacteria, which included (i) an anaerobic spirochaete, (ii) *Fusobacterium nucleatum*, (iii) *Peptostreptococcus* species (iv) Fastidious gram-negative anaerobe (possibly *Bacteroides fragilis*) were collectively responsible for the development of the typical pulmonary abscess. Since no single microorganism was able to cause this disease, this was a classic demonstration of bacterial synergy.

The euphoria caused by the discovery of antibiotics resulted in anaerobes being largely ignored. There were hardly any samples that were not contaminated and cultures for these microbes were rarely performed. Most lung abscesses were labeled as "nonspecific" because no pathogen could routinely be cultured from the sputum.[15] The decade of the 1970s was described by Bartlett[16] as the "renaissance" of anaerobic pleuropulmonary infections. It was during this period that specific sampling methods for anaerobic organisms were evolved. Simultaneously, culture methods too improved and bacteriologic confirmation became easy. Furthermore, the placement of different anaerobic microbes into an organized taxonomic order also helped in generating further interest in this field.

PATHOPHYSIOLOGY

Aspiration

Anaerobic infections of the lungs and their suppurative complications are mainly caused by the aspiration of bacteria that constitute the normal flora of the oral cavity. In the gingival crevice, the anaerobic microbes outnumber the aerobes by a ratio of 1000:1.[17] The concentration of anaerobes here approach geometric limits up to 10^{12}/gram.[17-19] It is well known that edentulous subjects have a lower risk of acquiring anaerobic lung infections. Although aspiration, especially during deep sleep, occurred in 45% of healthy individuals,[20] this phenomenon does not usually cause any disease. Normal bronchopulmonary defenses aid in clearing these aspirates. Any breach in such protective mechanisms facilitates an inflammatory process, thereby leading to disease. The frequency, volume and virulence of the anaerobic organisms in the inoculum aspirated are decisive in determining the pathology.

Aspiration is likely to occur in patients undergoing general anesthesia or having altered consciousness. At one point of time, aspiration was observed in one out of every six patients receiving general anesthesia.[21] The presence of artificial airways impairs glottic closure and makes the patient more vulnerable to aspiration. When aspiration is due to esophageal dysfunction or intestinal obstruction, the gastrointestinal tract is the likely source of the causative bacteria.[22,23] Several other conditions that predispose to clinically significant aspiration are responsible for anaerobic infections (Table 63.2).

Anaerobic Lung Infections and Dental Disorders

Persons with poor dental hygiene are prone to develop anaerobic infections of the respiratory tract. Suppurative periodontitis predisposes to aspiration as it harbors a potentially large quantity of anaerobic bacteria.[24] Any kind of anesthesia in the oropharynx, given for dental treatments, is also associated with a high chance of aspiration. Tooth extraction and scaling lead to a breach in the normal mucosal barrier, thereby further increasing the risk of aspiration.[25] It would be prudent for a pulmonologist to carefully extract a detailed dental history and also to examine the oral cavity for evidence of any inflammatory or suppurative disease while dealing with respiratory infections in order to evaluate for the presence of anaerobes.

TABLE 63.2: Predisposing conditions for anaerobic pleuropulmonary infections

1. Aspiration
    - i. Alcoholism
    - ii. General anesthesia
    - iii. Altered consciousness
        - a. Cerebrovascular accident
        - b. Drug overdose
        - c. Epilepsy
        - d. Smoke inhalation
        - e. Head trauma
    - iv. Dental disorders
        - a. Periodontal disease
            - i. Gingivitis
            - ii. Pyorrhea
        - b. Tooth extraction
    - v. Esophageal dysfunction or intestinal obstruction
2. Local underlying conditions
    - i. Pulmonary infarction
    - ii. Bronchogenic carcinoma
    - iii. Bronchiectasis
    - iv. Foreign body
3. Systemic underlying conditions
    - i. Diabetes mellitus
    - ii. Extrapulmonary malignancy
    - iii. Corticosteroids and other immunosuppresants
    - iv. Preceding antimicrobial therapy

[modified from ref. 57]

Other Predisposing Factors

Anaerobic lung infections can also occur following dissemination from preexisting extrapulmonary infections.[26-28] The classical example of this is Lemierre's syndrome,[26,29] which is almost always accompanied by secondary seeding, most commonly to the lungs. Subsequent to the introduction of effective antibiotics, the natural history of bacterial spread was interrupted and the incidence of such an infection reduced to a great extent. However, in the early 1970s, lung involvement was observed in 20 to 30% of the patients with *Bacteroides* bacteremia.[30,31] This could most probably have been due to penicillin-resistant strains of the genus *Bacteroides*, a phenomenon, which was discovered a few years later.

Necrosis of the lung tissue due to stasis is also associated with anaerobic infections. This commonly occurs in bronchiectasis, pulmonary infarction and postobstructive pneumonitis secondary to bronchogenic carcinoma or a foreign body. The other mechanisms that can cause anaerobic infections in the lungs and the pleural spaces include hematogenous and lymphatic spread and diaphragmatic translocation from subphrenic collections. Infection via the blood stream is noted in patients with septic thrombophlebitis of the jugular or pelvic veins.

NATURAL HISTORY AND CLINICAL CLASSIFICATION

The distinct clinical categories of anaerobic respiratory infections include pneumonitis, lung abscess, necrotizing pneumonia and pleural empyema. These different pathologic entities (Fig. 63.1) are believed to be the manifestation of different stages in the natural history of the infection. By and large, the predisposing event in most anaerobic lung infections is the aspiration of normal upper respiratory tract flora, seen in up to 90% of the patients.[16] The dependent portions of the lungs are the most commonly involved. In the supine position, either the posterior segments of the upper lobes or the superior (apical) segments of the lower lobes are involved. When aspiration occurs in the semirecumbent posture, the basal segments of the lower lobes are chiefly affected. The right lung is twice as commonly affected as the left since the right main bronchus is more aligned with the trachea.[32,33]

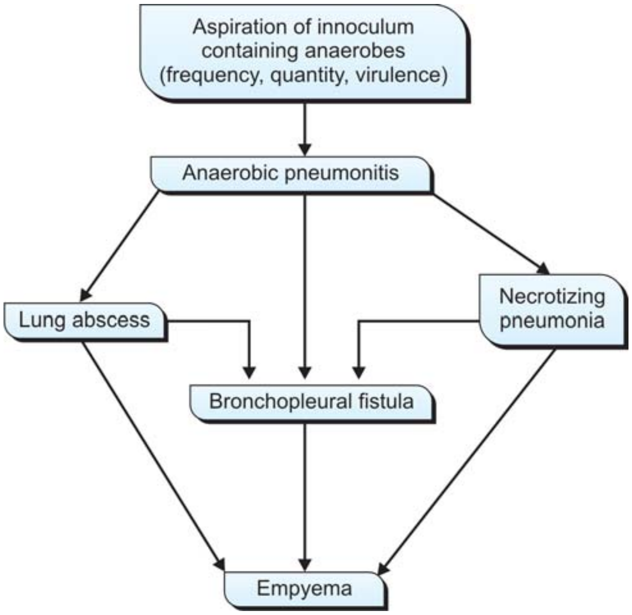

Fig. 63.1: Natural history of anaerobic pleuropulmonary infections

Acute Anaerobic Pneumonia

The earliest manifestation of anaerobic lung disease is pneumonia. The anaerobic etiology may not always be established due to similarities with acute bacterial pneumonias. However, the involvement of dependent segments could provide the initial hint. With appropriate therapy, the pathogenesis is arrested at this stage and the disease does not progress further towards suppuration.

Lung Abscess

Approximately 10 to 14 days later, necrosis and liquefaction in an area of anaerobic pneumonitis leads to the formation of a lung abscess.[34] A thick-walled cavity greater than 1 cm in diameter, often with an air-fluid level, develops within the pneumonic infiltrate.

Necrotizing Pneumonia

Necrotizing pneumonia is characterized by suppurative lung infiltrates with necrotic areas, leading to multiple small cavities (less than 1 cm in diameter); in comparison to a lung abscess, a greater number of pulmonary segments are involved. Such lesions, first described in 1905[35] and labeled as "pulmonary gangrene"[8] were often rapidly spreading and culminated in fatal lung destruction. Even though the incidence of necrotizing pneumonia reduced drastically after the introduction of antibiotics, the clinical response was unsatisfactory and mortality remained high.

Empyema

Empyemas are defined as the collection of pus in the pleural cavity. They result either after an ensuing bronchopulmonary fistula or as a direct extension from subpleural segmental pneumonitis. All the three clinical entities described above can be complicated by an empyema. Spread from infradiaphragmatic and subphrenic collections can also lead to the formation of empyema.

Chronic Anaerobic Pneumonitis

The term chronic anaerobic pneumonitis is used when there is no evidence of either parenchymal necrosis or pleural involvement. Histopathologic examination of such lesions reveals an intra-alveolar or an interstitial infiltrate.[36] Inability to procure an appropriate sample for identifying the causative bacteria renders this entity to be relatively uncommon.

Septic Emboli

Another rarely encountered disease process is the occurrence of septic emboli. Like necrotizing pneumonias, diffuse and discrete infiltrates that appeared due to embolization from anaerobic thrombophlebitis were documented mainly in the first half of the previous century.[37]

ANAEROBES AND UPPER RESPIRATORY SYNDROMES

Lemierre's Syndrome[29,38]

This disease, also known as postanginal sepsis and human necrobacillosis, is a form of thrombophlebitis of the internal jugular vein and is predominantly caused by *Fusobacterium necrophorum*. An acute oropharyngeal infection, leading to a putrid peritonsillar abscess is most often the trigger factor for this potentially destructive disease. Septicemic spread occurs primarily to the lungs and also to bones and joints. A triad of pharyngitis, neck swelling/tenderness and noncavitating lung infiltrates is described.[39]

Ludwig's Angina[40]

This is a periodontal infection arising from the tissues surrounding the lower third molar teeth. Although Ludwig's angina is most commonly caused by *Streptococcus*, polymicrobial infections with anaerobes have been noted in up to 40% of the cases.[41] The key features include marked local swelling over the floor of the mouth, which is usually associated with pain and trismus. Submandibular cellulitis ensues leading to impairment in swallowing. In the cases of glottis obstruction, leading to respiratory distress, tracheotomy may be lifesaving.

Vincent's Angina[42,43]

This is also termed as "trench mouth," heralded by an acute and sudden gingivitis. This progresses to the ulceration of the interdental papillae and necrosis of the gingivae. The most common pathogen is *Prevotella intermedia*. The acute necrotizing ulcerative gingivitis may spread occasionally to cause destruction of the buccal mucosa, teeth and the jaw bones.

INCIDENCE

For reasons more than one, it is not easy to calculate the true incidence of anaerobic lung infections. Sample collection techniques are difficult and appropriate culture methods may not be available in all laboratories. In addition, many patients respond to the initial empiric antibiotics even before specimens are obtained for confirmation.

Lung abscess and empyema are the two most frequently encountered forms of anaerobic pleuropulmonary infections. Prior to 1940s, almost all chronic pulmonary abscesses were either tuberculous or due to anaerobic bacteria. In three different case series, culture of abscess material obtained during surgical drainage or excision of the nontuberculous abscesses yielded anaerobic bacteria in 100% of the patients.[44-46] Landmark studies conducted during the 1970s showed that anaerobes accounted for more than 90% of all the lung abscesses.[47]

During the preantibiotic era, approximately two-thirds of all empyemas were caused by *Streptococcus pneumoniae*, while putrid fluid was aspirated in only 5% to 7% of the patients.[48] However, with the advent of antibiotics, in addition to a marked reduction in the incidence of empyemas, there was a significant alteration in the microbiological profile. During the decades of 1960s and 1970s, anaerobic microorganisms accounted for up to 40% of all patients with empyema.[49-55] A very high yield of 76% in one particular study was attributed to diligent case finding and processing of the samples in dedicated anaerobic research laboratories.[51]

In a prospective study on community and hospital-acquired cases of aspiration pneumonia, the community acquired cases were caused mainly by anaerobic organisms while approximately two-thirds of the hospital-acquired disease were due to aerobic bacteria.[56] Bartlett and Finegold[57] extensively reviewed all available literature on anaerobic pleuropulmonary infections and found that necrotizing pneumonias occurred in approximately a quarter of the patients during the preantibiotic era and in only 13.7% among the cases studied thereafter. Septic emboli were documented in 21% of patients reported prior to circa 1944 and in only 7.6% after effective antibiotics were prescribed. Not surprisingly, there were no cases of septic embolization among 70 cases detailed over a period of 14 years (from 1958 to 1971) at an anaerobic research center in California, USA.

The incidence of anaerobic infections in community acquired pneumonia (CAP) has not been studied in detail. Samples obtained by transtracheal aspiration (TTA) in 89 patients with CAP, implicated anaerobes in one-third of the patients.[58] In another study wherein quantitative cultures were performed on fiber optic bronchoscopy guided protected catheter specimens, anaerobes were recovered from 16 (22%) out of 74 patients.[59] In nosocomial pneumonia, it is not easy to establish anaerobes as the chief cause since patients are already receiving broad spectrum antibiotics before sample collection. When appropriate specimens were processed prior to empiric antibiotic therapy in 159 patients with hospital acquired pneumonia, anaerobes were identified in 56 (35%) of 159 patients.[60]

Although chronic anaerobic pneumonitis was produced in experimental animals,[13] there were hardly any clinical reports. During the last two decades, we have so far documented four patients (three adults and a child) with chronic anaerobic pneumonitis.[61-64] As is evident from the paucity of such a presentation, this chronic clinical category is yet to receive recognition that it deserves.

MICROBIOLOGY

The phenomenon of bacterial synergy, initially described by Smith in the 1920s, was repeatedly demonstrated in many studies on anaerobic lung infections. Way back in 1932,[65] bacteriological cultures performed on the thoracotomy aspirates of 16 patients with lung abscess grew anaerobic streptococci and anaerobic diphtheroids from all patients and *Bacteroides melaninogenicus* from 14 (88%). The other organisms identified included *Fusobacterium* species, *Bacteroides fragilis* and *Sphaerophorus necrophorus*. In subsequent large series[16,57,66] of anaerobic lung infections, the common microorganisms identified were peptostreptococci, *B. melaninogenicus* (now reclassified as *Prevotella melaninogenicus*) and *Fusobacterium nucleatum*. Given their predominance, this triplet is often referred to as the "Big Three" of anaerobic lung infections.[16] It was also noted that approximately one-third to half of the patients had mixed infections with potential pathogenic aerobes or facultative anaerobes as well. Another key pathogen is *B. fragilis* because of its inherent resistance to many of the commonly prescribed broad spectrum antibiotics. This organism was consistently cultured in up to 20% of adults and children with anaerobic lung infections.[16] This assumes clinical importance since *B. fragilis* is not a normal commensal in the oral cavity.

It is also well documented that the same bacteria can be recovered from patients with different clinical expressions, viz. pneumonitis, lung abscess, necrotizing pneumonia and empyema. The clinical course and subsequent development of suppurative complications is not determined by a specific anaerobe but by other non-microbiological factors.

As more anaerobes were identified, the taxonomy of anaerobic bacteria was revised during the last few decades. Many anaerobic streptococci and the genus *Peptococcus* were omitted in the current classification. Almost all clinically relevant species of *Peptococcus*, barring *Peptococcus niger*, were reassigned as *Peptostreptococcus*.[67] Based on lactic acid production, most peptostreptococci were grouped under the genus *Streptococcus*.[68] Many bacteria largely identified as *B. fragilis* were found to be other penicillin-resistant species of *Bacteroides*. Different bacteria grouped as *B. melaninogenicus* were reclassified as either *Prevotella* or *Porphyromonas*. Most of these species produced the enzyme penicillinase. The clinically important organisms that cause pleuropulmonary infections are highlighted in Table 63.3.

TABLE 63.3: Important anaerobic bacteria causing pleuropulmonary infections

Anaerobic gram-positive cocci
Peptostreptococcus
Streptococcus
Clostridium

CLINICAL FEATURES

The clinical spectrum of anaerobic pleuropulmonary infections ranges from an acute pneumonic process to a chronic indolent disease.[69] Based on the duration of symptoms and the disease pathology, the presentation can be divided into acute, subacute and chronic.

In patients with acute anaerobic pneumonitis without any associated suppuration, the clinical findings and the radiologic picture mimics acute pneumococcal pneumonia. When 46 patients with anaerobic pneumonitis were compared with another group of 46 patients with *Streptococcus pneumoniae* pneumonia, the key differentiating features included an absence of rigors, presence of conditions that predisposed to aspiration, and longer mean duration of presenting symptoms in those with anaerobic infections.[69] The common features include a febrile respiratory illness, peripheral leucocytosis and absence of bacteremia. Since the natural history of cavity formation and subsequent tissue necrosis takes about 7 to 14 days, the presentation of lung abscess and empyema is subacute and the median duration of symptoms is around two weeks.

Patients with chronic anaerobic pneumonitis usually present as an indolent disease with a protracted course. The mean duration of illness is usually weeks to months rather than a few days. Recurrent low grade fevers and weight loss are observed. In all of their patients,[61-64] the authors were able to isolate a small number of anaerobic pathogens in the culture, but they were unable to culture any aerobic organism in any patient. It is quite possible that the chronicity is due to selective but paucibacillary presence of anaerobes, unlike in other forms of anaerobic pleuropulmonary infections where there is associated polymicrobial aerobic growth. This prolonged and persistent illness mimics pulmonary tuberculosis, which is very common in our country.

Foul Smell

The association of anaerobes and putrid odor dates way back to 1893, when Veillon[70] observed foul smell in a pure culture of an "anaerobic" organism. Ever since the classical study of Altemeier[71] in 1938, foul smell is considered to be pathognomonic of anaerobic infections. The putridity is believed to be due to volatile short-chain fatty acids, which are the end products of anaerobic metabolism. However, some anaerobic cocci do not produce these volatile fatty acids.

While this characteristic feature is noted in approximately 50% to 60% of the patients with lung abscess, necrotizing pneumonia and empyema, the incidence of putrid sputum is only 5% to 18% in patients with acute anaerobic pneumonitis.[33] The absence of putridness does not exclude the possibility of anaerobic lung infections. None of their reported patients with chronic anaerobic pneumonitis[61-64] had foul smelling sputum.

LABORATORY DIAGNOSIS

Since the anaerobes have an inherent property of inability to survive in the atmosphere, it is not easy to obtain specimens for microbiologic examination. In order to establish the diagnosis, a strong coordination is needed between the clinician and the microbiologist. Appropriate specimens that have been collected stringently in order to avoid contamination should be expeditiously sent in an appropriate transport medium to the laboratory for specific anaerobic cultures.

Sampling Techniques

The collection of specimens for diagnosing anaerobic pleuropulmonary infections is based on the premise that the normal tracheobronchial tree is sterile below the level of the larynx. Expectorated sputum, nasopharyngeal aspirate, endotracheal or tracheotomy tube aspirates and unprotected bronchoscopic aspirates are rendered unsuitable for subjecting to culture methods as these specimens contain a significant amount of commensal anaerobic microbes. Pleural fluid and tissue samples collected during surgical procedures like thoracotomy and thoracoscopy are by and large uncontaminated but difficult to obtain. In order to procure an ideal and valid sample (Table 63.4) that is free of the anaerobic-rich oral flora, various specialized techniques have been described to obtain the specimen directly from the lower respiratory passages and beyond.

Transtracheal Aspiration (TTA)

As the name suggests, this technique involves collection of the specimen directly from the trachea. In doing so, the upper respiratory tract is bypassed thereby avoiding the contamination of the sample. First employed in the 1960s,[72-74] this soon became the procedure of choice in patients with pneumonia.[75] The task of procuring a reliable specimen was made much easier and recovery of anaerobes by this method was consistently demonstrated in many studies.[16,33,57] However, TTA is

TABLE 63.4: Respiratory specimens valid for culture of anaerobes

1. Transtracheal aspirate
2. Percutaneous transthoracic needle aspirate (under imaging guidance)
3. Empyema/pleural fluid
4. Protected fiberoptic bronchoscopic catheter brushing
5. Thoracotomy (open lung biopsy) specimen

[to be collected immediately in an anaerobic transport medium] no longer in vogue as this technique is fraught with complications and samples are rarely obtained prior to initiating empiric antibiotic therapy for "pneumonia."

Percutaneous Transthoracic Needle Aspiration

Transthoracic needle aspiration is another means of obtaining an uncontaminated specimen.[76] The best use of this technique was described from France in 1965[49] where culture of the aspirated material grew anaerobic bacteria in 22 out of 26 patients with lung abscesses. Although there are no large trials with this investigative modality, the advent of modern imaging techniques has resulted in this method being adopted as the procedure of choice in patients suspected to have anaerobic lung infections, including pleural collections. The authors employed this method under image guidance to establish the anaerobic etiology in two of their four documented patients with chronic anaerobic pneumonitis.[62,64]

Bronchoscopic Protected Catheter Brush

The use of bronchoscopic-protected catheter brush for the diagnosis of anaerobic lung infections was also advocated.[77-79] To further improve the bacteriologic yield, local anesthetic agents were restricted and lignocaine preparations without antibacterial additives were preferred.[80,81] The limitation of this procedure is that it may not always be feasible to perform before initiating antibiotic therapy. Moreover, quantitative cultures may not always be readily available.

Specimen Transport and Processing

Given the anaerobic nature of the organisms, it is essential to exercise extra caution while collecting and transporting the specimens. The samples should immediately be transferred into the tubes, which are free from oxygen gas.[82] Once the specimens reach the anaerobic laboratory, recovery of pathogenic bacteria should be ensured by appropriate processing. As expected, the yield of anaerobes was much higher when the specimens were analyzed in dedicated anaerobic research laboratories. When 25 specimens were simultaneously examined in a routine clinical microbiology laboratory and an anaerobic research laboratory, the etiologic bacteria were identified in all 25 specimens by the research laboratory and in only four by the routine laboratory.[57] Furthermore, in the specimens of these four subjects, a total of 14 anaerobes (i.e. 3.5 anaerobes per patient) were grown by the research laboratory while the clinical laboratory recovered only one organism per patient. A negative culture of a potential specimen containing anaerobic organisms can occur due to several factors (Table 63.5).

TABLE 63.5: Causes of failure to culture anaerobes from potential specimens

1. Prolonged air exposure during collection, transport and processing
2. Failure to perform Gram staining so as to obtain the initial clue
3. Failure to utilize satisfactory selective and differential culture media
4. Overdependence on fluid thioglycollate medium
5. Failure to hold anaerobic cultures for a prolonged time

[adapted from ref. 57]

Gram Staining and Culture Methods

Performing Gram's staining of the obtained specimens gives a rapid clue about the class of anaerobic bacteria responsible for the disease. Even staining of expectorated sputum, which is far from ideal sample for diagnosing anaerobic infections, would help in determining whether anaerobes are the causative organisms or not. The microscopic appearances of some of the common anaerobes, as visualized after Gram staining, are quite characteristic (Table 63.6).

Cultures performed on invariably "contaminated" samples containing dense anaerobic flora of the upper respiratory tract are usually meaningless. However, growth of normal oral commensals may be an indication of anaerobic lung infection. The specimens should be inoculated on at least three different culture media to get a definitive growth of anaerobic bacteria. In order to achieve an etiologic diagnosis in as many of the specimens thus obtained, quantitative cultures were applied.[83-85] Newer techniques like gas liquid chromatography have helped in detecting the metabolic end products of anaerobic bacteria.

TABLE 63.6: Appearance of anaerobic bacteria on Gram's stain

P. melaninogenicus:	Pale staining gram-negative coccobacillus
B. fragilis:	Pale, some what pleomorphic gram-negative bacillus
F. nucleatum:	Pale, gram-negative bacillus with pointed ends
Peptostreptococcus:	Small, gram-positive cocci, usually in chains
Veillonella:	Very small, gram-negative cocci in clumps, pairs or short chains

RADIOLOGICAL MANIFESTATIONS

The radiological findings depend on the stages of involvement during the natural history of the disease. Patterns in pneumonia can range from subsegmental infiltrates to bilateral multilobar consolidation. A review of the radiological features in patients with anaerobic pulmonary and pleural infections revealed that approximately 50% of the patients had lung parenchymal involvement while other 30% had pleural empyemas without lung disease, the remaining 20% had combined parenchymal and pleural shadowing.[86] Half of the lung parenchymal abnormalities consisted of consolidation while the other 50% were either lung abscesses or necrotizing pneumonias. A radiologic worsening was noted in all patients during the initial three days and in one-third of the cases, during the first week.

In our four documented patients with chronic anaerobic pneumonitis,[61-64] right lung involvement (Fig. 63.2) was noted in two patients and in the other two the left lung was affected. Radiological progression from pneumonitis to lung abscess after initiation of therapy was noted in 20% to 30% of patients.[69,86] Mediastinal and hilar lymphadenopathy has also been reported in a patient with anaerobic lung abscess.[87] Gas producing organisms can cause a pyopneumothorax.[88]

TREATMENT

During the first half of the previous century, when antibiotics were yet to be discovered, the main therapeutic measures included the postural drainage of lung abscesses and surgical management of empyemas. The main drugs used were arsenicals[89-91] and sulphonamides.[92,93] This was supplemented with adequate rest and proper nutrition.[94]

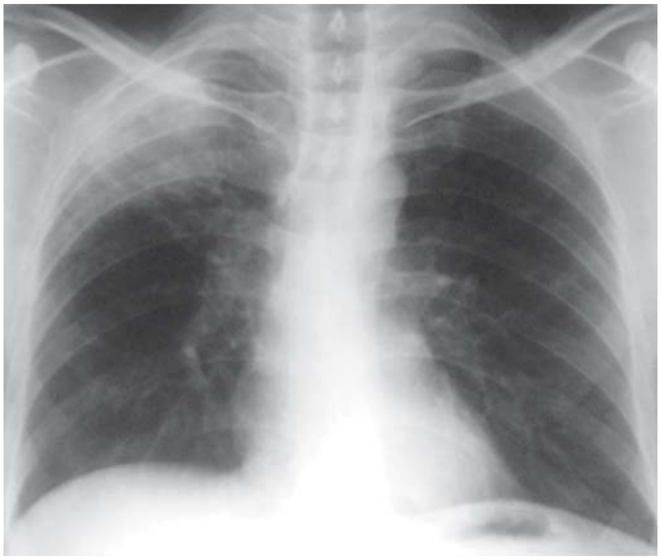

Fig. 63.2: Chest roentgenogram showing nonhomogeneous opacity in the right upper lobe in a patient with chronic anaerobic pneumonitis[64]

Subsequent to the advent of antibiotics, the prognosis improved significantly. During the initial few decades, penicillin G was the treatment of choice for more than half of the cases. Phenoxymethylpenicillin was often used during the follow-up period. Alternative antibiotics used then included lincomycin, chloramphenicol, tetracycline and erythromycin.[95,96] The clinical category of anaerobic lung infections was the deciding factor for usage of combinations, as well as dosage and duration of treatment. Since necrotic lung tissue is relatively avascular, a lower than the required dose would probably result in progressive damage. This could lead to suppurative complications and metastasis to other organs, e.g. cerebral abscess. Insufficient duration of therapy was responsible for a high relapse rate and distant seeding.[97]

Metronidazole too showed good bactericidal activity *in vitro* against anaerobes and initial results were encouraging.[98,99] Other advantages of this drug included 100% oral bioavailability and a substantially lower cost of therapy. After initial promising results, studies with metronidazole were discouraging. Collective data on 28 patients from three studies revealed therapeutic failures in 12 (43%) cases.[100-102] This poor performance was due to the fact that aerobic and microaerophilic streptococci are resistant to metronidazole. In another study[103] spanning six years, clinical success was noted when metronidazole was used in combination with penicillin or amoxicillin.

During the same period, better clinical efficacy of clindamycin in comparison to lincomycin was demonstrated.[104] In 1983, Levison and colleagues,[105] published the first large scale prospective trial wherein clindamycin (1800 mg/day) was compared with penicillin G (6 million units/day). There were no failures with clindamycin, while one in every five patients treated with penicillin did not show a satisfactory response. The mean duration of foul smelling sputum and fever were significantly lower in the clindamycin group. In patients with anaerobic pleuropulmonary infections, these studies led to the endorsement of three different regimes in circa 1984 by the consultants of the "Medical Letter," which include[106] (i) penicillin G, (ii) clindamycin and (iii) metronidazole + penicillin. Subsequently, a randomized controlled trial[107] comparing clindamycin versus penicillin in 37 patients with anaerobic lung infections confirmed the efficacy of clindamycin when a failure rate of 44% with penicillin and only 5.3% with clindamycin was demonstrated. The specimens of nine patients eventually grew penicillin-resistant strains of the genus *Bacteroides*, five of whom had been randomized to the penicillin arm. The authors concluded that clindamycin should be the initial choice for empiric treatment. The authors have documented the occurrence of isolates from a patient with anaerobic lung abscess that were resistant to penicillin and metronidazole.[108]

In recent times, although the efficacy of several new antibiotics has been demonstrated in community-acquired pneumonia, the role of these drugs in bacteriologically confirmed lung abscess and empyema has not been systematically studied. Most of these agents show excellent activity against common aerobic respiratory pathogens including the trio of "atypical" organisms. Amongst the fluoroquinolones, moxifloxacin and gemifloxacin have good *in vitro* activity against anaerobic organisms.[109,110] Although ticarcillin and piperacillin, the semisynthetic penicillins, possess substantial antianaerobic properties,[111,112] up to 30% of beta-lactamase producing anaerobic gram negative bacilli, especially *B. fragilis*, are resistant to this group of drugs.[113] Imipenem, which belongs to the carbapenem group, is highly effective against beta-lactamase, producing *B. fragilis*.[114] The suggested dosages of common antianaerobic drugs are given in Table 63.7. Antibiotics should be continued until symptoms have subsided, any fluid collection has resolved or stabilized and there is appreciable radiological clearing.[115] A minimum duration of two to three weeks is recommended.[116]

Surgery

Surgical drainage is the cornerstone for the management of patients with empyema. However, the frequency of surgery for lung abscess reduced drastically once effective antibiotics became available. In comparison to approximately half of the patients requiring surgical treatment for pulmonary abscess during the preantibiotic era,[117] 40 years later only 10% to 14% patients needed intervention.[118-120] In patients with lung abscess and necrotizing pneumonia without pleural involvement, the indications for surgery include failure of antibiotics and life-threatening hemoptysis. A lobectomy may also be indicated, if an underlying malignancy is suspected. When surgery is contraindicated due to comorbid conditions, percutaneous catheter drainage is helpful in alleviating the symptoms.[121]

TABLE 63.7: Suggested antianaerobic drugs and dosage

Antimicrobial Agents	*Dosages (per day)*
Penicillin G	10 to 20 million units (IV/IM)
Metronidazole	400 mg, 3 times a day (oral)
Clindamycin	600 mg, 3-4 times a day (oral)
Chloramphenicol	500-1000 mg, 4 times a day (oral)
Amoxycillin + clavulanate	500 mg + 125 mg, 3 times a day (oral)
Ticarcillin + clavulanate	3 gm + 100 mg, 3-4 times a day (IV)
Piperacillin + tazobactum	4 gm + 500 mg, 3 times a day (IV)
Imipenem	500 mg, 3-4 times a day (IV)

[Dosages to be adjusted as per the patients' profile]

PROGNOSIS

After the introduction of antibiotics, most patients have had a favorable outcome with the overall mortality rate reducing from 34% to 10% over time.[16] Fatal disease processes like necrotizing pneumonia and septic emboli are rarely seen. A delayed clinical response is noted in subjects with empyema and cavitary disease, especially if the cavity is greater than 6 cm in diameter. Morbidity in such patients does not improve until drainage of fluid is achieved or cavitary closure occurs over time. Other factors responsible for a poor prognosis include a chronic presentation beyond two months, elderly age group, bronchial obstruction, nosocomial aspiration and associated serious comorbidities. In the largest series of 193 patients,[16] mortality directly due to the anaerobic infection was observed in 4% while in another 7%, the disease process triggered a downhill course that eventually culminated in death.

CONCLUSION

The bacterial flora of the oral cavity is predominantly anaerobic. These commensal organisms have the propensity to cause disease in people prone to aspiration. Unfortunately, anaerobes as a key cause of pleuropulmonary infections are largely overlooked. The clinical and radiological features are often mistaken, which increases morbidity. In a patient with poor orodental hygiene and a history suggestive of aspiration along with radiological picture compatible with involvement of the dependent pulmonary segments, pulmonologists must exclude anaerobic lung infections.

Bronchial Asthma—Epidemiology

SK Jindal

INTRODUCTION

Asthma, although known since antiquity, remains a disease of wide heterogeneity and variability. It has been differently understood in different cultures at different times. Some descriptions are available in the ancient Ayurvedic, Greco-Roman, Chinese and Egyptian literature.[1] The word "asthma" is derived from the Greek word, which meant "to pant heavily" or "gasp for breath." In Hindu Vedic medicine, it was known as "Tamaka Swasa."

DEFINITION

There is no uniform agreement on its definition in spite of the fact that the problem is recognized and appreciated by even the lay, all over the world. For a clinician, it is characterized by episodic wheezing, breathlessness and/or cough. Functionally, there is widespread narrowing of the intrapulmonary airways and demonstrable, reversible obstruction. Pathologically, it is a chronic inflammatory disorder of the airways. Description of asthma, proposed by the Global Initiative for Asthma (GINA), is presently the most accepted and understood definition:[2]

"Asthma is a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role. The chronic inflammation is associated with Airway Hyper-Responsive (AHR) that leads to recurrent episodes of wheezing, breathlessness, chest tightness and coughing particularly at night or in early morning. These episodes are usually associated with widespread, but variable airflow obstruction within the lung that is often reversible either spontaneously or with treatment."

The operational definition as above is fairly broad and comprehensive, but lacks precision. This is particularly difficult from an epidemiological point of view for the assessment of burden and comparative analysis.

EPIDEMIOLOGY

There is a marked variability in the global prevalence rates. It is reported to involve from about 1% to over 20% individuals in different populations.[2-4] An overall global asthma burden of about 300 million patients had been previously estimated based on the then prevalence rates.[3,5]

Prevalence rates from India and several other Asian countries have been reported to generally, lie between 2 to 5% in most countries.[4,6-10] The absolute burden is however enormous, considering the density of population in the Asian region, especially in India, China and Bangladesh, which comprise a large chunk in this region. The Indian estimates, based on the average, 2.05% prevalence of current asthma was 21 millions for all age groups, in the total population of 1.028 billion individuals in 2001[9] (See Chapter 34 on The Burden and Clinical Spectrum of Respiratory Diseases).

ECONOMIC BURDEN

There is a huge economic burden of asthma on both the individual and the society.[11-14] The burden is related to the direct costs of management and indirect losses due to school and work absenteeism.[15,16] The costs of "not treating" or mistreating asthma are even higher.[17]

The data available on economic burden in India is rather sparse. An attempt at assessment was made on the basis of prevalence rates available in different studies.[18] The estimated total annual cost of about ₹ 32 billion for patients with chronic asthma with additional costs of about ₹ 5 billion for acute asthma (for the year 2011)[18] is an enormous burden for the health care infrastructure of a developing country.

EPIDEMIOLOGICAL DIFFERENCES

The wide range in prevalence rates of different populations is partly "true" and partly attributable to methodological differences. Most importantly, the definition of asthma employed in different studies is the major determinant. There are epidemiological differences in the diagnosis of "current asthma", "ever-asthma" or presence of airway hyper-responsiveness. The different clinical symptoms and signs used for diagnosis may often overlap and are difficult for interpretation in community studies. For example, wheezing is reported almost twice as often as asthma. Therefore, history of wheezing used for diagnosis of asthma is frequently misleading, especially in case of children. An overlapping diagnosis of chronic bronchitis and Chronic Obstructive Pulmonary Disease (COPD) is also an important mimic of asthma in adults. The sensitivities and specificities of the questionnaires and/or other objective test, used for diagnosis of asthma are also different. One-time single assessment of airway obstruction by the measurement of Peak Expiratory Flow (PEF) or other spirometric indices cannot be used for the diagnosis of asthma and airway reversibility is difficult to perform in the field studies. Validation and standardization of the study methodology are therefore, of great importance for meaningful and comparative assessments.

FACTORS INFLUENCING PREVALENCE OF ASTHMA

True differences in the prevalence of asthma can be attributed to several ethnic, genetic, geographical, occupational and environmental differences. A host of these factors would influence the occurrence of asthma.

The prevalence of asthma is influenced by several risk factors, which can be broadly categorized into the host and the environmental factors that influence the development of asthma (Table 64.1). The development is largely determined by host factors, while the triggering is mostly caused by environmental exposures. Some of the factors from both the host and the environmental groups may also overlap in their roles and cause asthma development, as well as the trigging of symptoms.

TABLE 64.1: Important risk factors that influence the development of asthma

A. Host factors
    1. Age and sex
    2. Socioeconomic status
    3. Racial and ethnic factors
    4. Genetic polymorphisms
    5. Other atopic conditions
    6. Obesity
B. Environmental factors
    1. Aeroallergens
    2. Infections (? Protective role)
    3. Occupational exposures
    4. Environmental pollutants
    5. Outdoor pollution?
    6. Indoor pollution
        - Environmental tobacco smoke/In utero exposure to smoke
        - Solid fuel combustion
    7. Diet: Processed foods
        Breastfeeding (Protective role)

Host Factors

Age and Sex: On an average, asthma occurs with equal frequency in both sexes. There is a male predominance in children, being twice as common in boys as in girls before 14 years of age.[19] The sex difference disappears as the age advances, to a higher incidence in women in adults.

Asthma is more common in children in the 5 to 14 years age groups. Being a chronic disease, the cumulative prevalence of asthma increases as the age advances. The earlier belief that "children often grow out of asthma" is not factually true. Although from about a third to half of the children may become asymptomatic as they grow, the disease cannot be labeled as "eliminated." A large number of these children develop symptoms later in life.

Genetic Factors: There is a strong genetic predisposition of asthma. The presence of a family history of asthma and other allergies in the first degree relatives of patients, indicates the role of genetic factors. Identical twins were found to have a very high relative risk (17.9) of asthma in a study on cumulative incidence of asthma in twins.[20] The evidence was strongly considered in favor of the genetic predisposition.

No single gene defect is identifiable in asthmatic patients. However, multiple genetic polymorphisms associated with clinical asthma and/or BHR have been identified, some of which may actually affect the bronchodilator responsiveness.[21-24] Various other genes are found to modify the treatment response to antiasthma drugs, including the bronchodilators, corticosteroids and leukotriene modifiers.[25-28]

Genetic factors are important determinants of susceptibility to allergic diseases and asthma. Recent studies have highlighted their role in determining the in utero development and early life susceptibility to allergies.[29] This has resulted in better endophenotying, prognostication and prediction of treatment responses.[29] It can be therefore, anticipated that the gene polymorphism may play an important role in future in planning and improving the management of asthma.[27-30]

Other Host Factors: Asthma is known to differ in prevalence in different racial and ethnic populations. Some of these differences could actually be attributed to different genetic polymorphisms. Common environmental exposures may also influence the prevalence differences.

Presence of nasal (allergic rhinitis) and skin (atopic dermatitis) atopies, sinusitis and nasal polyposis is frequently associated with asthma. They possibly share a common genotyping and pathogenesis. Nasal allergy in particular is said to exist with asthma as an essential companion—“one airway–one disease” (Chapter 65).

Presence of obesity is also a recognized risk factor.[31] Obesity is partly genetic and partly environmental in origin. In obesity, asthma is supposedly mediated through the release of leptins.

Environmental Factors

Several environmental exposures, such as aeroallergens, occupational agents, tobacco smoke, outdoor and indoor air pollutants and possibly infectious agents have been implicated in the development of asthma. Some of these agents may also act as “precipitating” or “aggravating” factors (triggers) for clinical symptoms of asthma.

Allergens: The role of allergens in asthma development is not entirely clear. Many air borne pollens, fungal spores, home dust mite, insect debris, cat and dog dander have been implicated as independent risk factors for asthma.[32-35] Early exposure to cat and dog dander has been reported as protective against allergen sensitization in some studies, while others suggest that it increases the risk.[35-37]

Infections: Infections are important triggers of asthma symptoms. Respiratory Syncytial Virus (RSV) and parainfleunza virus infections are known to cause asthma in children.[38] On the other hand, early childhood infections are reported to protect from asthma (Hygiene hypothesis),[39] possibly explaining the lower asthma prevalence in the developing countries, including in India, attributable to higher occurrence of childhood infections. The “hygiene hypothesis” is based on the concept that exposure to airway infections and allergens early in life causes maturation of T-helper 1 (Th 1) lymphocytes over Th-2 lymphocytes, thereby decreasing the risk of allergies.[40] The theory has been further supported by some studies, but not by others.[41,42] The issue remains unresolved. Genetic susceptibility of an individual may also contribute to this development of asthma.

The common organisms, which have been cultured from bronchoalveolar lavage samples are the viruses (adenovirus, parainfluenza, RSV and influenza), mycoplasma and Chlamydia. They may have important role in asthma development, airway inflammation and remodeling.[43] Of various parasites, only hook worm infestations have been shown to reduce the risk.[44]

Occupational Exposures: Exposure to chemical vapors, irritant gases, metal fumes and other exhausts amongst persons engaged in different occupations may cause airway sensitization and increased production of IgE, which commonly manifest as occupational asthma.[45-47] Occupational sensitization is also responsible for both the development and precipitation of asthma.

Occupational asthma occurs mostly in adults, generally after an exposure period of month to years in sensitized individuals.[48,49] (Also see Chapter 111). Both IgE mediated and cell-mediated immunological reactions are involved.[50]

Environmental Pollution and Smoking: Exposure to environmental air pollutants in both outdoor and indoor conditions is an important cause of respiratory morbidity and increased asthma exacerbations.[51] Domestic combustion of solid fuel for cooking and heating is an important cause of indoor air pollution in India as well as in several third-world countries. Combustion exhausts are responsible for increased respiratory infections as well as lung function impairment in children. However, the role of environmental pollutants in the development of asthma remains debatable.[52]

Passive exposure to tobacco smoking, an important source of indoor air pollution Environmental Tobacco Smoke (ETS), is another important cause of increased asthma morbidity amongst both children and adults.[53-55] There is no good evidence to attribute the development of asthma to ETS exposure. However, in utero exposure of the fetus to smoking from a smoker mother is reported to influence the lung development. In utero tobacco smoke exposure is also shown to be responsible for persistent wheezing problems in children in the first year of life.[56]

Diet: Foods are commonly blamed to aggravate asthma in India, but scientific evidence is inadequate.[57] There are some data to suggest the role of processed foods, contributing to the increased incidence of asthma.[58] Breast milk fed infants have been shown to have lower incidence than those fed with formula milk or soy proteins.[59]

Asthma involves a complex interplay of different mechanisms, which result in a common clinical presentation of widespread airway obstruction. There are huge epidemiological and clinical variations in the disease spectrum. Several of these differences are perhaps based on different inflammatory phenotypes, which are now unfolding.[60,61]

Allergic Rhinitis, Asthma and Comorbidities

Ruby Pawankar, Satoko Kimura, Sachiko Mori, Yukiko Yokoyama

INTRODUCTION

Allergic Rhinitis (AR) and asthma are the most common atopic diseases with an increasing prevalence during the last decades.[1-4] Allergic rhinitis is an IgE-mediated inflammation of the nasal mucosa and IgE-mediated inflammation of the airways can either manifest as AR, asthma or both. However, the vast majority of patients with asthma have rhinitis, and rhinitis is a major independent risk factor for asthma in cross-sectional and longitudinal studies.[5-7] While the temporal relation of allergic rhinitis and asthma diagnoses may be variable, allergic rhinitis often precedes asthma. Moreover, AR is linked to other comorbid conditions like chronic hyperplastic eosinophilic sinusitis, nasal polyposis and serous otitis media.

Over 400 million patients worldwide suffer from AR and 300 million people suffer from asthma. Both AR and asthma are chronic inflammatory diseases of the airways and their inflammatory mechanisms are characterized by an inflammatory infiltrate made up of eosinophils, T cells and mast cells that release several mediators, chemokines and cytokines, local and systemic IgE synthesis, and a systemic link via the bone marrow. Studies have shown that patients with AR exhibit Bronchial Hyperresponsiveness (BHR) and increase in inflammatory cells, and that nasal allergen challenge further increases this hyperreactivity.[8,9] This potential link may be due to cross talk between the upper and lower airway, the direct impact of inflammatory mediators released locally and to the systemic link between the two.

Although cardinal structural differences exist between the nose and the lungs, the relationships between rhinitis and asthma can be viewed under the concept that the two conditions may be the manifestations of one syndrome, the “chronic allergic respiratory syndrome.” Moreover, the impact on costs, frequency of emergency room visits, hospitalization and quality of life is greater if AR is associated with asthma as compared to asthma alone[10,11] and treating AR in patients with asthma, and comorbid AR has shown to reduce hospitalization by 61%.[12]

Inflammation in AR

Upon allergen exposure, sensitized mast cells degranulate within minutes to release preformed and newly synthesized mediators that include histamine, proteases, cysteinyl leukotrienes (CysLTs), prostaglandins and cytokines; some of which induce the characteristic early-phase symptoms of AR, while others orchestrate the late-phase response via the infiltration of inflammatory cells, like eosinophils, basophils and T cells, into the nasal mucosa.[13-14] This infiltration of inflammatory cells can also be orchestrated by T-helper type 2 (Th2) cells within the local microenvironment. The subsequent release of additional mediators from these inflammatory cells, including histamine and CysLTs, sustains the inflammatory characteristic of the late-phase reaction. In chronic ongoing allergen inflammation, mast cells exhibit increased histamine releasability consequent to the enhanced FcεRI expression (increased numbers of IgE receptors) and surface-bound IgE, as well as the enhancement of signal transduction pathways.[14-18] While these processes together induce the phenomenon of priming, mast cells in patients with AR also express increased levels of β1 integrins and activation via the integrin receptors results in an enhanced release of inflammatory mediators even in the presence of lower amounts of allergen.[14-18] This process may, in part, contribute to the phenomenon of nasal hyper-responsiveness.

Link Between Allergic Rhinitis and Asthma

Epidemiology and Trigger Factors

Allergic rhinitis and asthma are closely linked based on a variety of parameters ranging from epidemiologic, immunologic and clinical evidences.[19] Epidemiologically, upto 40% patients with allergic rhinitis have comorbid asthma and up to 80% of patients with asthma experience nasal symptoms. Furthermore, in a study assessing the burden of allergic rhinitis in children, the prevalence of asthma was 3-fold higher in those children who had allergic rhinitis at baseline.[20] The trigger factors of AR, like indoor and outdoor allergens, can also cause asthma.

Inflammation and Pathomechanisms

Both AR and asthma are inflammatory diseases and their inflammatory mechanisms are similar in a way that they are characterized by an inflammatory infiltrate made up of eosinophils, T cells and mast cells that release several mediators, chemokines and cytokines, local and systemic IgE synthesis, and a systemic link via the bone marrow. Typical early- and late-phase responses are also common features to both rhinitis and asthma. Studies have shown that patients with AR exhibit BHR and increased number of inflammatory cells in their bronchial mucosa.[8,9] This increase in bronchial inflammation in response to allergen-induced rhinitis might contribute to the exacerbations of asthma frequently seen in individuals with underlying AR. Experimental studies in patients with Seasonal Allergic Rhinitis (SAR) without asthma have demonstrated an upregulation of adhesion molecule expression, eosinophil infiltration in both the upper and lower airways, after nasal allergen challenge and increased bronchial hyper-reactivity.[21] These results demonstrate that an allergic nasal reaction produces systemic inflammatory changes.

Systemic Inflammation in Allergic Rhinitis

AR is not associated with just localized inflammation of the nasal mucosa but also has a systemic component to it. This may explain in a significant way the mechanisms underlying the rhinitis-asthma link. Thus in patients with AR, allergen exposure results in the activation of immune cells, including Th2 lymphocytes. Some of these Th2 cells migrate to the bone marrow, where they stimulate the bone marrow to produce and recruit inflammatory cells, i.e. basophils, eosinophils and mast cell precursors to the inflamed target tissues. The selective recruitment of inflammatory cells into the lower airways can occur only in those individuals, with at least subclinical inflammation in the lower airways, in whom specific adhesion molecules, such as vascular cell adhesion molecule 1 and chemoattractants, such as TARC, eotaxin, are already upregulated. This parallel relationship is influenced by many interactions between the nose and the lower airways in that the nose plays a major homeostatic role by conditioning inhaled air, but perhaps even more important is the bidirectional interaction that results from the systemic inflammation that is produced after local allergic reactions.

Therapeutic Outcomes of Treating AR in Asthma

Several studies have shown that treating comorbid allergic rhinitis results in a lowered risk of asthma-related resource utilizations and hospitalizations.[12] For patients with asthma, the presence of comorbid allergic rhinitis is associated with higher total annual medical costs as well as increased likelihood of asthma-related hospital admissions and emergency visits.[10,11] Thus, there is a clear evidence that comorbid allergic rhinitis can be an indicator marker for more difficult-to-control asthma or poor asthma outcomes. In a recent international survey on the impact of concomitant AR and asthma on patient health and quality of life, the presence of AR in children with asthma disrupted their lives by limiting their ability to get a good night's sleep, concentrate at work/school or enjoy social activities and that when AR symptoms flared up, asthma symptoms worsened.[22] Corren et al. reported that nasal symptoms of subjects exposed to a "cat room" were more severe if they had concomitant asthma than if they had rhinitis alone.[23] These findings highlight the potential for improving asthma outcomes by treating comorbid AR.

Yet there are individuals who suffer only from rhinitis but not asthma. The precise reason for this is not completely known but can be presumed that these patients might have a milder form of the disease. Therefore, the relationships between rhinitis and asthma can be viewed under the concept that the two conditions are manifestations of one syndrome, the chronic allergic respiratory syndrome, in two parts of the respiratory tract. At the low end of the syndrome's severity spectrum, rhinitis appears to be the sole manifestation, although pathologic abnormalities in the lower airways are already present. At the higher end, rhinitis is worse and the lower airways disease becomes clinically evident. Once manifested, the two conditions track in parallel in the terms of severity.[24]

However, AR is often underdiagnosed and undertreated due to the lack of appreciation of the disease burden and its impact on the quality of life, socially at school and in the workplace and its huge economic burden. Thus, there was clearly a need for a global evidence-based document that would highlight the interactions between the upper and lower airways, including diagnosis, epidemiology, common risk factors, management and prevention. The Allergic Rhinitis and its Impact on Asthma (ARIA) document was first published in 2001 as a state-of-the-art document for the specialist, the general practitioner and other health care professionals.[25]

Allergic Rhinitis and its Impact on Asthma (ARIA)

In 1999, during the ARIA, WHO workshop, an evidence-based document was produced using an extensive review of the literature available up to December 1999. The statements of evidence for the development of ARIA followed WHO rules and were based on those of Shekelle et al.[26]

The ARIA document was intended to be a state-of-the-art review for the specialist as well as for the general practitioner and other health care professionals:

- To update their knowledge of AR.
- To highlight the impact of AR on asthma.
- To provide an evidence-based documented revision on the diagnosis methods.
- To provide an evidence-based revision on the treatments available.
- To propose a stepwise approach to the management of the disease.

The ARIA Classification of Allergic Rhinitis

Allergic rhinitis was previously classified into seasonal, perennial and occupational. Perennial allergic rhinitis is usually caused by indoor allergens such as dust mites, molds, insects (cockroaches) and animal danders. Seasonal allergic rhinitis is related to a wide variety of outdoor allergens such as pollens or molds.

However, from a therapeutic point of view, it is often difficult to differentiate between seasonal and perennial symptoms. Some seasonal allergens cause perennial symptoms, some perennial allergens may cause symptoms only during certain periods of the year and the majority of patients are now polysensitized to seasonal and perennial allergens. Therefore, a new classification to provide a better description of allergic rhinitis has been proposed by the ARIA as "intermittent" or "persistent" rhinitis[25] (Fig. 65.1). The severity of allergic rhinitis on the other hand can be classified as "mild" or "moderate-severe" on the basis of symptoms as well as the quality of life of the patient. Several studies have now validated this classification.[27,28]

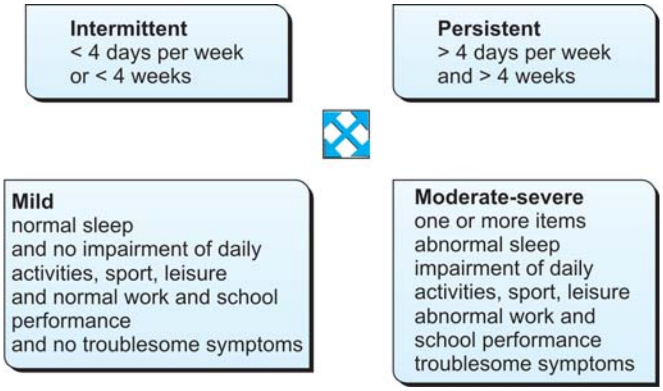

Fig. 65.1: The new ARIA classification

ARIA Update

The pharmacological treatment of AR proposed by ARIA is an evidence-based and stepwise approach depending on the classification of the symptoms and comprises of patient education, allergen avoidance, pharmacotherapy and validated allergen-specific immunotherapy. Nonsedating, second-generation antihistamines are the mainstay in mild-to-moderate intermittent and persistent AR. As a step-up, Intranasal Corticosteroids (INCS) may be added. Intranasal corticosteroids is the first line in moderate-severe persistent AR. However, subsequent research and increasing knowledge have resulted in the ARIA 2008 update which includes new information on existing therapies as well as newer therapies like anti-IgE mAb and antileukotrienes with a new level of evidence for pharmacotherapy and increasing information on the link between the upper and lower airways. Most importantly ARIA emphasizes that successful management of both rhinitis and asthma requires an integrated view of the airways and an integrated approach of treatment.

The ARIA update was commenced in 2004. Several chapters of ARIA were extensively reviewed using the Shekelle evidence-based model and papers were published in peer-reviewed journals: Tertiary prevention of allergy, complementary and alternative medicine, pharmacotherapy and anti-IgE treatment, allergen-specific immunotherapy, links between rhinitis and asthma and mechanisms of rhinitis. There was then a need for a global document that would highlight the interactions between the upper and lower airways, including diagnosis, epidemiology, common risk factors, management and prevention. Moreover, the allergy perspective should also be targeted towards developing countries. Thus, the ARIA 2008 update was published.[29-33]

One important aspect of the ARIA update was to consider the comorbidities of AR and in particular, asthma. Epidemiologic studies have consistently shown that asthma and rhinitis often coexist in the same patients in every region of the world. The vast majority of patients with asthma have rhinitis, but the prevalence of asthma in rhinitis patients still needs to be assessed. Adults and children with asthma and documented concomitant AR experience more asthma-related hospitalizations and physician visits and incur higher asthma drug costs than adults with asthma alone. These patients also experience more frequent absence from work and decreased productivity. However, some studies have not shown such an association.

Many patients with AR have an increased bronchial reactivity to methacholine or histamine, especially during and sometime after the pollen season. Nasal and bronchial inflammation is often related, but remodeling of the nose and bronchi appears to differ.

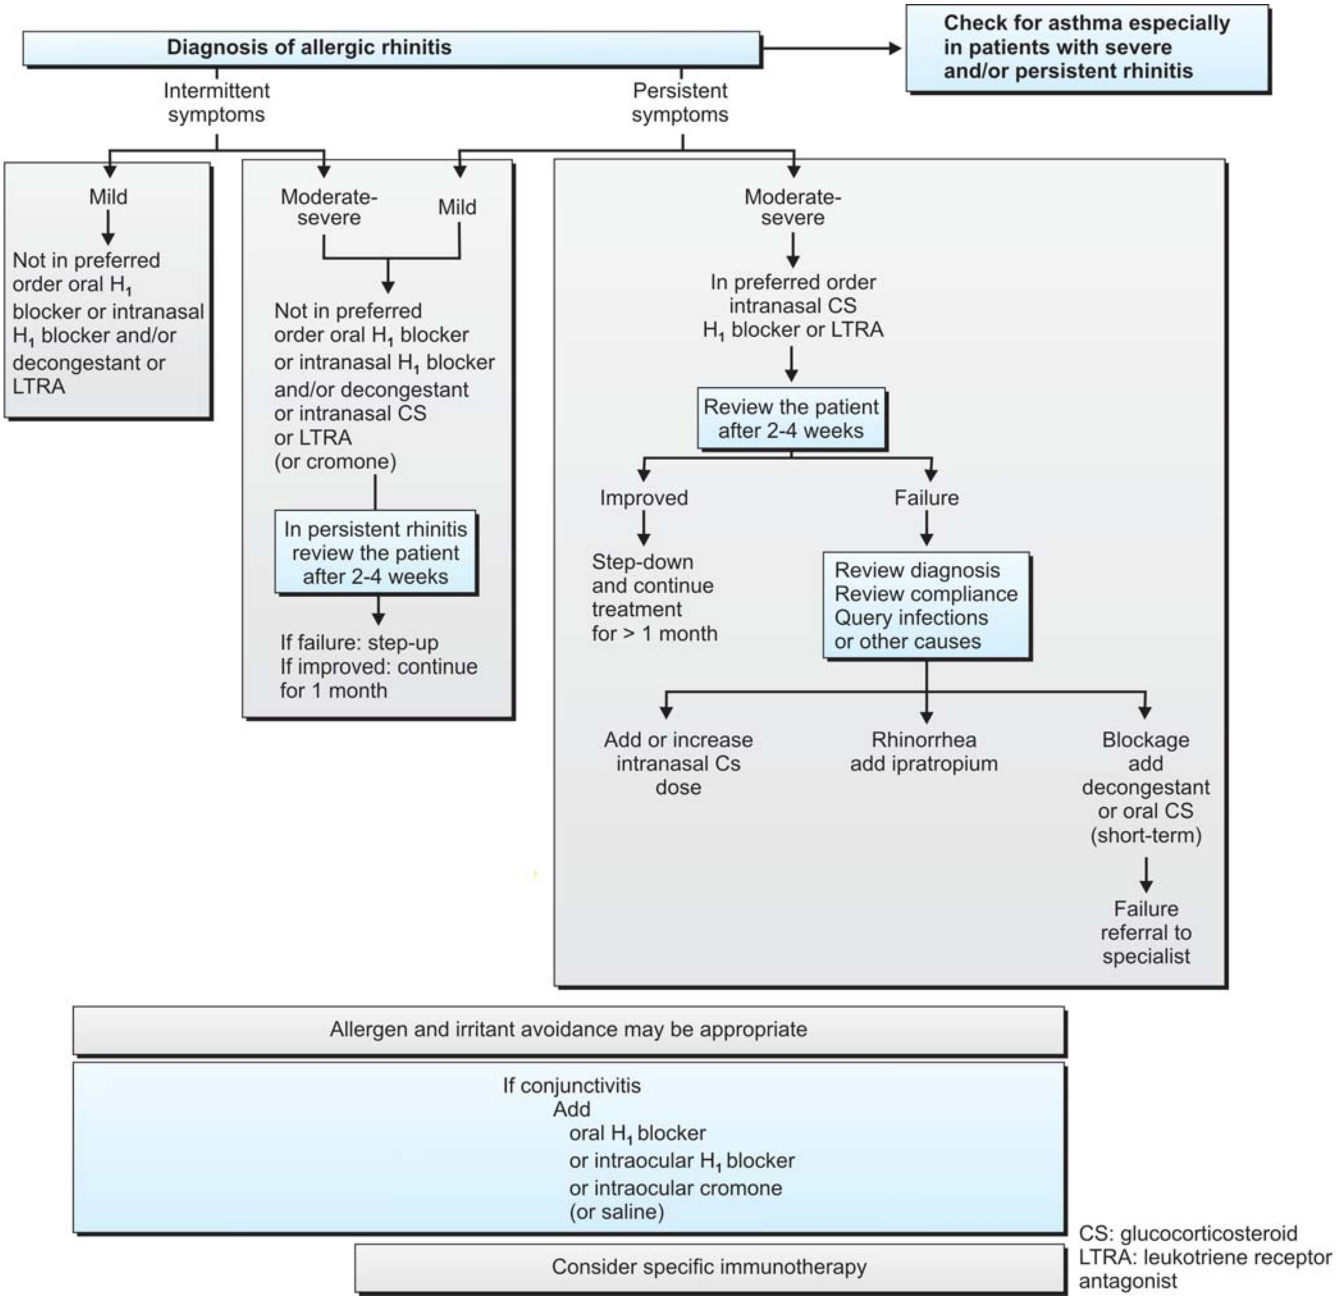
A large list of treatments was considered in the ARIA 2008 update. Concerning pharmacologic treatments, intranasal corticosteroids are recommended as the first-line therapy in patients with moderate-to-severe disease and are also effective on ocular symptoms, H_1-antihistamines of the second generation are important treatments for all patients and leukotriene receptor antagonists are particularly important for patients with rhinitis and asthma. On the other hand, tertiary prevention of allergy is still a matter of debate since clinical trials do not usually show any efficacy of single allergen avoidance measures. Allergen-specific immunotherapy in patients with AR has a prolonged preventive effect on the development of asthma when stopped. Sublingual allergen-specific immunotherapy has proven to be a safe and effective treatment,[34] but clinical trials need to be standardized. Mechanistic studies have repeatedly demonstrated that Sublingual Swallow Immunotherapy (SLIT) is able to affect the T response by modulating some of the activities of T regulatory cells. Recent studies have shown the dose-dependency of the clinical effects of SLIT and the magnitude of the effect over placebo largely exceeded the 20% suggested threshold, required for defining an immunotherapy as clinically effective and that SLIT has been formally shown the capability of reducing both the direct and indirect costs of the disease. A new World Allergy Organization (WAO) consensus document on SLIT has summarized the state-of–the-art on SLIT with relevant recommendations.[35] Specific immunotherapy, allergen avoidance and pharmacotherapy have come to be the recommended form of treatment for allergic diseases, both in adults and children. An algorithm of the management of AR is provided (Fig. 65.2).

Other Comorbidities of AR

Allergic rhinitis is linked to other comorbid conditions like rhinosinusitis, nasal polyps, sleep disturbances like Obstructive Sleep Apnea (OSA) and otitis media with effusion (Fig. 65.3). As many as 70% of patients with AR reported suffer from nasal and ocular symptoms. Acute sinusitis is found to be more common in patients with AR and Eustachian tube obstruction has been shown to increase in the peak season in patients with seasonal allergic rhinitis. AR interferes with sleep and leads to increased daytime sleepiness. Allergic rhinitis patients reported difficulty falling asleep, nocturnal awakening, early awakening, nonrestorative sleep, lack of sleep and snoring. The treatment of allergic rhinitis is shown to improve coexisting conditions, including conjunctivitis, asthma, rhinosinusitis, otitis media with effusion and sleep disorders.

CONCLUSION

Allergic asthma and rhinitis are manifestations of the atopic syndrome. Epidemiologic, experimental and clinical data underline the importance of this link. Although the diseases commonly occur together, it is still unclear why some allergic patients develop only asthma and others only rhinitis. The reason for the variety in clinical expression of allergic airway disease is not known. Besides a genetic predisposition, environmental factors contribute to the development of the allergic phenotype. Local and systemic inflammatory processes also seem to be involved. However, their exact contribution to the clinical picture of airway allergy still remains to be elucidated. Although it is clear that the condition of the upper airways has an impact on lower airway physiology, the mechanisms underlying this relation are far from being resolved. To date, most data



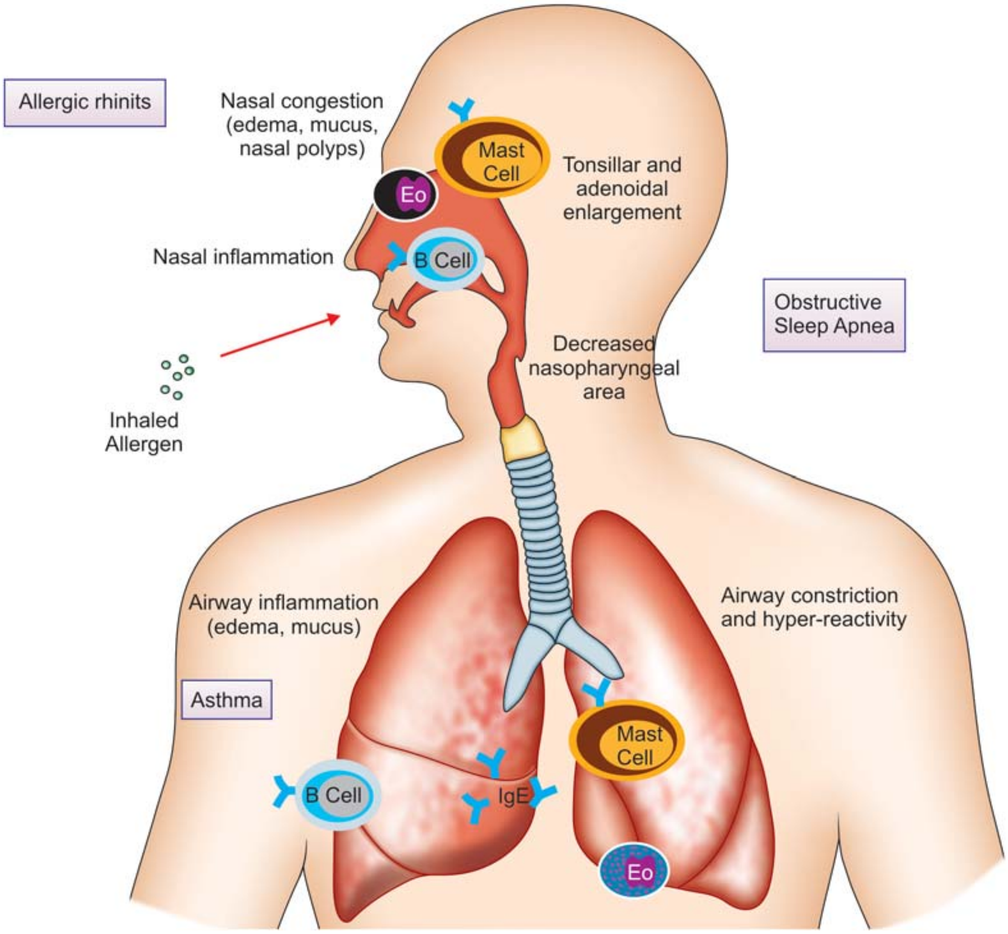
Diagnosis of allergic rhinitis
Check for asthma especially in patients with severe and/or persistent rhinitis
Intermittent symptoms
Persistent symptoms
Mild
Not in preferred order oral H1 blocker or intranasal H1 blocker and/or decongestant or LTRA
Moderate-severe
Mild
Not in preferred order oral H1 blocker or intranasal H1 blocker and/or decongestant or intranasal CS or LTRA (or cromone)
In persistent rhinitis review the patient after 2-4 weeks
If failure: step-up
If improved: continue for 1 month
Moderate-severe
In preferred order intranasal CS H1 blocker or LTRA
Review the patient after 2-4 weeks
Improved
Failure
Step-down and continue treatment for > 1 month
Review diagnosis
Review compliance
Query infections or other causes
Add or increase intranasal Cs dose
Rhinorrhea add ipratropium
Blockage add decongestant or oral CS (short-term)
Failure referral to specialist
Allergen and irritant avoidance may be appropriate
If conjunctivitis
Add
oral H1 blocker
or intraocular H1 blocker
or intraocular cromone
(or saline)
Consider specific immunotherapy
CS: glucocorticosteroid
LTRA: leukotriene receptor antagonist

Fig. 65.2: The algorithm for the treatment of AR recommended by ARIA

point towards a systemic link between upper and lower airways involving bloodstream and bone marrow.

The socioeconomic burden via annual costs of treating asthma and AR—both direct costs (hospitalization, medications) and indirect costs (time lost from work, premature death)—are substantial and represent an even heavier burden in societies with emerging economies. In eight countries in the Asia-Pacific, the annual per-patient direct costs ranged from US $108–1,010, total per-patient costs, including productivity costs, ranged from US $184–1,189.[36]

The recommendations of the ARIA workshop in 1999 are still valid with respect to the ARIA update and in particular, it is recommended that all patients with AR, particularly if it is persistent, should be evaluated for asthma. AR is not only a risk factor for underlying



Allergic rhinits
Nasal congestion (edema, mucus, nasal polyps)
Mast Cell
Eo
Tonsillar and adenoidal enlargement
Nasal inflammation

Asthma Diagnosis

Liesel D'silva, Parameswaran Nair

INTRODUCTION

Correct diagnosis of asthma is the first step towards achieving disease control. To establish a diagnosis of asthma, the clinician should determine that episodic symptoms of airflow obstruction or airway hyperresponsiveness are present; airflow obstruction is at least partially reversible; and alternative diagnoses are excluded. The guidelines recommend the use of a detailed medical history, a physical examination and spirometry. Additional pulmonary function studies, bronchoprovocation tests, measures of allergic status, chest radiography and specific blood tests are not routinely necessary but may be useful when considering alternative diagnoses. Over the last 15 years, there has been increasing interest in the noninvasive biomarkers of airway inflammation as an adjunct to the assessment of clinical asthma control.

CLINICAL DIAGNOSIS

Medical History

A detailed medical history of the new patient who is known or thought to have asthma should address the following items (Table 66.1):[1-3]

Physical Examination

Physical examination may reveal findings (Table 66.2) that increase the probability of asthma, but the absence of these findings does not rule out asthma because asthma symptoms are variable. Therefore examination of the respiratory system may be normal during asymptomatic periods.[1]

TESTS FOR DIAGNOSIS AND MONITORING

In 1891, Lord Kelvin (Kelvin L, 1883) emphasized the importance of measurements by stating that "When you can measure what you are speaking about and express it in numbers, you know something about it; but when you cannot measure it, when you cannot express it in numbers, your knowledge is of a meager and unsatisfactory kind."

Symptoms are nonspecific and can result from variable airflow limitation, inflammation, moderate or severe chronic airflow limitation or other respiratory and nonrespiratory conditions. There are poor correlations between symptoms and airway function or airway inflammation and between airway function and inflammation. Reliance on symptoms alone could lead to misdiagnosis and under or over treatment. Therefore measurements are critical to understanding and individually treating airway disease such as asthma.[6]

Measurements of Lung Function

Although the diagnosis of asthma is usually based on the presence of characteristic symptoms, patients with asthma frequently have poor recognition of their symptoms. If their asthma is long standing they also have poor perception of symptom severity.[7] Physicians may also be inaccurate in their assessment of symptoms such as dyspnea and wheezing.[8,9] Therefore, measurement of lung function provides an objective confirmation of the

TABLE 66.1: Medical history in asthma

Symptoms that occur or worsen in the presence of precipitating factors	Recurrent cough Wheezing Shortness of breath Chest tightness Sputum production
Pattern of symptoms	Perennial, seasonal or both Continual, episodic or both Onset, duration, frequency (number of days or nights, per week or month) Diurnal variations, especially nocturnal and on awakening in early morning Colds go to the chest or take more than 10 days to clear up Symptoms improve by appropriate asthma treatment
Precipitating and/or aggravating factors	Viral respiratory infections Environmental allergens, indoor (e.g. mold, house-dust mite, cockroach, animal dander, mosquito repellants such as Type I synthetic pyrethroids) and outdoor (e.g. pollens, congress grass) Characteristics of home including age, air conditioning system, wood-burning stove, carpeting, over concrete, presence of molds or mildew, presence of pets with fur, characteristics of rooms where patient spends time (e.g. bedroom and living-room with attention to upholstery) Smoking, environmental tobacco smoke Exercise Occupational chemicals or allergens Environmental change (e.g. moving to new home; going on vacation; and/or alterations in workplace, work processes or materials used) Irritants (e.g. tobacco smoke, strong odors, air pollutants, occupational chemicals, dusts and particulates, vapors, gases and aerosols) Emotions (e.g. fear, anger, frustration, hard crying or laughing) Stress (e.g. fear, anger, frustration) Drugs (e.g. aspirin; and other nonsteroidal anti-inflammatory drugs, beta-blockers including eye drops, others) Food (e.g. black gram), food additives, and preservatives (e.g. sulfites) Changes in weather, exposure to cold air Endocrine factors (e.g. menses, pregnancy, thyroid disease) Comorbid conditions [e.g. sinusitis, rhinitis, nasal polyposis, gastroesophageal reflux disease, obesity, pulmonary tuberculosis*, allergic bronchopulmonary aspergillosis, obstructive sleep apnea, Churg-Strauss syndrome (very rare)]
Development of disease and treatment	Age of onset and diagnosis History of early-life injury to airways (e.g. bronchopulmonary dysplasia, pneumonia, parental smoking) Progression of disease (whether the disease has got better or worse) Present management and response to therapy, including management of exacerbations Frequency of using Short-acting beta2-Agonist (SABA) Need for oral corticosteroids including dose and frequency of use
Family history	History of asthma, allergy, sinusitis, rhinitis, eczema, or nasal polyps in close relatives
Social history	Social factors that interfere with adherence: Substance abuse Social network Level of literacy Ability to afford the medication Employment status
History of exacerbations	Usual prodromal signs and symptoms Rapidity of onset Duration Frequency Severity [need for urgent care, hospitalization, Intensive Care Unit (ICU) admission]

Contd...

Contd...

	Life-threatening exacerbations (e.g. intubation, ICU admission) Number and severity of exacerbations in the past year Usual management (what has worked in the past to treat the exacerbation)
Impact of asthma on patient and family	Episodes of unscheduled care (emergency department visits, urgent care, hospitalization) Number of days missed from school/work Limitation of activity, especially sports and strenuous work History of nocturnal awakening Effect on growth, development, behavior, school or work performance and lifestyle Impact on family routines or activities Economic impact
Assessment of patient's and family's perceptions of disease	Patient's, parent's and spouse's knowledge of asthma and belief in the chronicity of asthma and in the efficacy of treatment Patient's perception and beliefs regarding use and long-term effects of medications especially inhaled corticosteroids Ability of patient, parents or spouse to cope with the disease Level of family support and patient's, parent's or spouse's capacity to recognize severity of an exacerbation Economic resources Sociocultural beliefs

* Presence of additional symptoms of fever, expectoration or chest pain should raise the suspicion of pulmonary tuberculosis. Any patient who presents with cough of more than three weeks duration should have the sputum examined for pulmonary tuberculosis.[4,5]

TABLE 66.2: Physical examination in asthma

System	*Physical examination findings*
Upper respiratory tract	Increased nasal secretion, mucosal swelling, deviated nasal septum, nasal polyp, tenderness over sinuses, ear discharge, oral candidiasis (because of inhaled corticosteroid therapy)
Chest	Wheezing, wheezing during prolonged phase of forced exhalation In severe asthma exacerbations: Wheezing may be absent, cyanosis, drowsiness, difficulty in speaking, tachycardia, hyperinflated chest, use of accessory muscles, intercostal retraction Chronicity of asthma could lead to appearance of hunched shoulders, chest deformity
Skin	Atopic dermatitis, eczema

diagnosis of asthma, measures severity of airflow limitation, its reversibility and variability.

Of the various methods available to assess airflow limitation, spirometry, particularly the measurement of Forced Expiratory Volume in One Second (FEV_1), and Forced Vital Capacity (FVC) and Peak Expiratory Flow (PEF) measurement are widely accepted for use in patients over 5 years of age.[1]

Predicted values of FEV_1, FVC and PEF based on age, sex and height have been obtained from population studies. With the exception of PEF for which the range of predicted values is too large, they are useful to assess whether a given value is abnormal or not. Caucasian prediction equations are most commonly used for the interpretation of the results of routine spirometry in India; however a study[10] was undertaken to assess the interchangeability of Caucasian and north Indian prediction equations while interpreting routine spirometric data. The use of Caucasian prediction equations resulted in poor agreement with Indian equation in most height and age categories among both men and women. One of the reasons suggested was that the lung volumes in Indian subjects are approximately 10% smaller than corresponding values in Caucasians.[11] Therefore one needs to assess the most appropriate prediction equation for use in one's own clinical practice after considering ethnic differences in spirometric values.

Spirometry

Forced Expiratory Volume in 1 second (FEV_1) and FVC are measured during a forced expiratory maneuver using a spirometer. Variable airflow limitation of asthma is recognized objectively by the presence of SABA reversibility of FEV_1, i.e. greater than or equal to 12% and greater than equal to 200 ml from the prebronchodilator value;[12] however many asthma patients may not exhibit this reversibility at each assessment especially if they are on treatment. It is advisable to repeat the test at different visits. As spirometry is effort-dependent, proper instructions on how to perform the forced expiratory maneuver must be given to the patients and the highest of the three recordings selected. Spirometry should be accurately performed on appropriate equipment by trained personnel with monitoring of quality control.[12]

Spirometry with FEV_1 and VC values is an initial requirement and is better than PEF because it is more sensitive and discriminates between obstructive and non-obstructive ventilatory defects. FEV_1/FVC ratio less than 0.75 to 0.80 in adults and less than 0.90 in children suggests airflow limitation.[12]

Normal spirometry does not rule out asthma in a patient with a history of asthma-like symptoms or in a patient taking asthma controller medications.[13] Spirometry is often useful for excluding the possibility of Chronic Obstructive Pulmonary Disease (COPD)[14] and spirometry may reveal that asthma is more poorly controlled (i.e. a low FEV_1) than suggested by the frequency of symptoms and use of a rescue inhaler reported by the patient.[15] A low FEV_1 is also a strong predictor of a subsequent asthma exacerbation particularly in children.[16] FEV_1 can be measured accurately even during acute asthma attacks and helps to determine the need for hospitalization.[12,17]

Some of the common reasons for limited widespread use of spirometry include the lack of availability, a false belief that the test does not reveal additional information; “too time consuming” in a busy clinical practice or difficulty in interpretation of the test. General practitioners should be encouraged to use spirometry in their clinical practice.[18,19]

Peak Expiratory Flow (PEF)

Although spirometry is the preferred method of documenting airflow limitation, PEF monitoring is valuable to confirm the diagnosis of asthma and to monitor the disease particularly in patients who are poor perceivers of symptoms, and to identify occupational causes of asthma symptoms.[20] There are different methods of calculation for within-day variability and between-day variability in PEF, which may be documented in patient diaries.[20,21]

One of the most common methods for calculation of “within-day variability” is the following:

$$\frac{\text{Day's highest PEF value} - \text{Day's lowest PEF value}}{\text{Mean PEF}}$$

A diurnal variability of more than 8% suggests a diagnosis of asthma.

One of the most common methods for calculation of “between-day variability” is the following:

$$\frac{\text{Lowest morning PEF over 1-2 weeks}}{\text{Highest PEF}}$$

This index increases as PEF variation decreases.

Peak expiratory flow measurements are made with peak flow meters, which are relatively inexpensive, portable, plastic instruments that can be used by patients at home. However, PEF measurements are not interchangeable with FEV_1[22,23] and can underestimate the degree of airflow limitation. As the range of predicted values for PEF is too wide when measured with different peak flow meters, PEF measurements should be compared to the patient’s own previous best measurements using his/her own peak flow meter.[24] PEF measurements are effort dependant and careful instruction is required to reliably measure PEF.

Key Recommendations for Clinical Practice

Encourage patients to record and monitor their lung function in a diary for the diagnosis of asthma.
The upper limit of normal for diurnal variability in PEF is 8% and not the traditionally believed cut-point of 15% to 20%.
Normal lung function does not exclude a diagnosis of asthma.
Perform lung function measures accurately, on appropriate (calibrated) equipment, by trained personnel, and monitor quality control.
Enter actual values of lung function in the medical records (not just normal or abnormal).
Use the same peak flow meter on each occasion to compare PEF measurements within the same patient.

Measurements of Airway Responsiveness

When patients have symptoms consistent with asthma, but normal lung function, measurements of airway responsiveness to direct or indirect bronchoprovocation challenges are frequently used to establish a diagnosis of asthma; however bronchoprovocation challenge tests are not readily available in clinical practice. The direct bronchoconstrictors act on the airway smooth muscle receptors to induce bronchoconstriction. The indirect bronchoconstrictors involve an intermediate pathway, such as osmotic or non-osmotic mediator release from inflammatory cells, sensory nerve stimulation, and perhaps others and include exercise and Eucapnic Voluntary Hyperpnea (EVH), hypertonic saline, distilled water, adenosine monophosphate and the newest challenge test which is dry powder mannitol.[25] Direct airway responsiveness has been measured primarily by histamine and methacholine. Histamine and methacholine produce near identical responses on a milligram for milligram or millimole for millimole basis;[26] however histamine is now used infrequently because of a greater prevalence of adverse effects, such as cough, flushing and occasional syncope.[25]

Direct Challenges

Methacholine challenge is a highly sensitive test. Two of the most commonly used methods are the tidal breathing method and the dosimeter method.[27] Doubling concentrations of methacholine up to 16 mg/ml (higher for research purposes) are inhaled at five minute intervals from the start of one inhalation to the start of the next. Single measurements of FEV$_1$ are made at 30 and 90 seconds. The percent reduction in FEV$_1$ is compared with post saline FEV$_1$, and the test is continued until there has been a 20% or more decrease in FEV$_1$ or until the maximum concentration has been administered. The results are expressed as the provocation concentration causing a 20% FEV$_1$ decrease (PC$_{20}$ for the tidal breathing method and PD$_{20}$ for the dosimeter method). A sigmoid log dose-response curve is recorded. The normal range of PC$_{20}$ is greater than or equal to 8 mg/ml,[28] while that for PD$_{20}$ is greater than or equal to 7.8 µmol.[29]

A positive methacholine challenge is consistent with, but not diagnostic of asthma. When a patient has current symptoms, a negative methacholine challenge result excludes asthma with reasonable certainty.[25] Methacholine challenge is of limited value in guiding treatment in patients with isolated cough because a positive methacholine challenge result does not predict response to asthma therapy[30] and a negative methacholine challenge result fails to identify individuals with eosinophilic bronchitis and, does not predict nonresponse to asthma therapy.[31] Serial monitoring of methacholine challenge may serve as a useful guide in asthma therapy,[32] but is valuable as a guide to diagnose occupational asthma.[33]

Indirect Challenges

Indirect airway challenges[34] such as exercise and EVH, hypertonic saline and dry powder mannitol create a hyperosmolar airway milieu, leading to the release of inflammatory cell mediators from mast cells and basophils. Ultrasonic nebulized distilled water is a hypoosmolar stimulus that also causes mediator release but is infrequently used. Adenosine Monophosphate (AMP) results in inflammatory cell mediator release by non-osmotic mechanisms.

In contrast to the direct challenges, the indirect challenges are more specific and thus more valuable for confirming a diagnosis of asthma. Indirect challenges may be preferred for the diagnosis of occupational asthma; however this needs further study.[25] Although the indirect challenges are not sensitive enough to exclude a diagnosis of asthma, the utility of the mannitol challenge test in this area requires further study. Indirect challenge tests are the challenges of choice to evaluate individuals who may have exercise-induced bronchoconstriction and as a guide to monitor asthma treatment. A normal mannitol challenge result in a treated asthmatic patient should be taken as an indication to consider tapering of treatment. On the other hand, a persistent positive mannitol challenge result would indicate that treatment should not be tapered and might even suggest that treatment could be increased.[35]

Normalization of the mannitol challenge result with inhaled corticosteroids has the potential to become a treatment goal.[36]

Key Recommendations for Clinical Practice

Histamine and methacholine challenge tests should be made more available to general practitioners through hospitals or other pulmonary function test laboratories.

It is important to increase the availability of methacholine inhalation tests in general practice because this is where milder disease occurs; patient presents with symptoms but spirometry is normal, which could commonly result in misdiagnosis.

A normal histamine or methacholine challenge test only reflects the current status of the patient.

Normal results do not exclude past asthma which might have been reversed completely by the avoidance of allergen or occupational sensitizer, the clearing of infection or by corticosteroid treatment. In this situation, if current symptoms are present, they are of another cause than asthma.

Noninvasive Markers of Airway Inflammation

Airway inflammation (bronchitis) is an important component of all diseases of the airways of the lungs, including asthma. The inflammation has various causes (inhaled allergens, occupational chemical sensitizers, reduction of corticosteroid treatment, cigarette smoking, air pollution, bacterial or viral infections).[37] These different causes result in different types of inflammation which cause different clinical presentations and respond differently to the treatment. The use of traditional methods to indirectly assess airway inflammation from symptoms, use of reliever medication, peripheral blood eosinophilia and spirometry is problematic and, even among specialists, is frequently inaccurate.[38] Hence its measurement is beneficial, especially in specialist practice where disease is often more severe, complicated and difficult to control.

A number of noninvasive measures (in sputum, blood, urine, exhaled air) have been evaluated in clinical trials, of which only exhaled nitric oxide and quantitative sputum cell counts have reached clinical practice.[39] Use of these markers in practice is supported by published data, the GINA guidelines (since 2008) and Canadian asthma treatment guidelines (since 2007). Therefore, we will focus on these two markers in this chapter.

Although included in recent treatment guidelines, quantitative sputum cell counts and exhaled nitric oxide are available only at a few centers around the world. They are not more widely available because the introduction of new procedures into practice is difficult and physicians cannot appreciate the need for them when they are not available to use. Also, there is a perceived unpleasantness of sputum induction and skepticism related to patient and physician satisfaction with the results of cell counts.

Quantitative Sputum Cell Counts

Spontaneous or induced quantitative sputum cell counts provide the most valid, reliable, reproducible, comprehensive and specific measure of airway inflammation.[40] Sputum induction is safe,[41] has a success rate of more than 80% in adults;[42] however the success rate is somewhat lower in children, and induced sputum may not be possible in children of less than 8 years.[43] Low lung function (FEV_1 less than 1 L) is a relative contraindication.[44]

Two methods have been used to induce sputum with an aerosol of hypertonic saline from an ultrasonic nebulizer. In one, the subject is pretreated with inhaled salbutamol to protect against airway constriction that could be caused by inhalation of hypertonic saline.[45] The concentration of saline and duration of inhalation is either 3% for up to 20 to 21 minutes or 3%, followed by 4%, followed by 5% each for seven minutes. In the other method,[46] 4.5% hypertonic saline is given without pretreatment and inhaled for doubling times from 30 seconds to eight minutes. Sputum plug or whole sputum can be processed with the aid of a mucolytic dithiothreitol.[47] A stained cytospin is examined to obtain a differential inflammatory (eosinophils, neutrophils, macrophages, lymphocytes and epithelial cells, expressed as a percentage based on a manual count of 400 cells) and total inflammatory cell count, cell viability and squamous cell contamination. The induced sputum supernatant can be used to assay molecular markers of inflammation and has contributed significantly to our understanding of the mechanisms of airway disease.[44] Spontaneous or induced sputum may be collected and have generally shown no differences in total or differential cell counts or concentrations of inflammatory mediators.[48] Fifty one to eighty two percentage of spontaneous samples have an adequate cellular viability of more than 40%.[42]

The procedure is not difficult. Sputum can be induced by a pulmonary function technologist. A dedicated hematologically or cytologically trained technologist can process and examine quantitative sputum cell counts. Sputum induction takes about 30 minutes; the results take 1.5 hour to obtain and involve 1 hour of the technologist's time.[39] A questionnaire survey demonstrated that induced sputum cell counts was well accepted by patients and physicians,[49] which further supports the need for their implementation into routine clinical practice, particularly for specialists. Normal values for total and differential cell counts (total cell count of less than 9.7 million cells/g of sputum and proportion of neutrophils less than 64% and eosinophils less than 1.1%) have been well established in healthy subjects.[50]

Sputum cell counts identify different inflammatory subtypes of bronchitis such as eosinophilic (usually normal total cell count, percentage of sputum eosinophils ≥ 1.1%), neutrophilic (total cell count of ≥ 9.7 million cells/g of sputum and proportion of neutrophils ≥ 64%), mixed granulocytic (total cell count ≥ 9.7 million cells/g of sputum and proportion of eosinophils and neutrophils ≥ 1.1% and ≥ 64% respectively) and trivial neutrophilia of unknown significance (an isolated rise in total cell count of ≥ 9.7 million cells/g of sputum or proportion of sputum neutrophils ≥ 64%).[42]

Bronchitis can be heterogeneous during stable (eosinophilic 36%, neutrophilic 14%, mixed granulocytic 6%, trivial neutrophilia 16% , normal cell counts 28%) and exacerbated asthma (eosinophilic 35%, neutrophilic 21%, mixed granulocytic 13%, trivial neutrophilia 16% , normal cell counts 15%).[42] In approximately 50% of the patients, quantitative sputum cell counts can change during successive exacerbations in the same patient.[51]

Eosinophilic bronchitis is usually noninfective. There is strong evidence that sputum eosinophilia (> 3%) is a predictor of clinical improvement with corticosteroid treatment.[52] Monitoring sputum eosinophils benefited patients with moderate to severe asthma by reducing the number of eosinophilic exacerbations and decreasing the severity of all exacerbations without increasing the total inhaled corticosteroid dose.[53] In contrast, neutrophilic bronchitis is usually infective in nature; however the intensity of neutrophilia tends to differ from the trivial neutrophilia of cigarette smoking or pollutants to mild/modest and intense neutrophilia usually associated with viral and bacterial infections respectively.[39,54] When we do not have sputum cell counts to identify the type of bronchitis, it is standard practice to treat presumed infective exacerbations of asthma with both additional antibiotic and corticosteroid treatment. However most infective exacerbations are considered to be viral and will be unresponsive to antibiotic. Also corticosteroid treatment will only be expected to improve eosinophilic and not non eosinophilic exacerbations.[55]

Sputum cell counts should be examined at least twice a year in stable disease and during exacerbations; quantitative cell counts should be repeated after treatment of an exacerbation with additional corticosteroid and/or antibiotic treatment. Determining the inflammatory subtypes of bronchitis with quantitative sputum cell counts will avoid the inappropriate use of antibiotics (and reduce possible antibiotic resistance) or corticosteroids (and reduce their side effects including the potentiation of infection) and eventually lead to better management of asthma, reduce the overall cost of therapy[56] and improve the quality of life of these patients.

Exhaled Nitric Oxide

Nitric oxide is a biological mediator that plays many important physiological and pathological roles. It is synthesized from the amino acid L-arginine by the enzyme Nitric Oxide Synthase (NOS). There are three different isoforms of NOS in the human body, of which the calcium-independent, Cytokine-inducible NOS (iNOS) is the predominant isoform involved in the production of nitric oxide in the airways. Inducible NOS is present in airway epithelial and inflammatory cells of asthma patients and has been implicated in the pathogenesis of asthma. There is an upregulation of iNOS in the airways of asthmatics as part of the inflammatory response. This increased iNOS activity is responsible for an increase in exhaled nitric oxide.[57]

Fractional concentration of exhaled nitric oxide (FeNO) is best measured before spirometric maneuvers at an exhaled rate of 50 ml/second maintained within 10% for more than six seconds and with an oral pressure of 5 cm to 20 cm H_2O to ensure velum closure. The results are expressed as NO concentration in ppb based on the mean of two to three values within 10%.[58]

The exact relationship between fractional concentration of exhaled nitric oxide and the underlying pathology in asthma remains unclear.[59] Although there is an increasing use of FeNO as a surrogate marker for the presence of clinically relevant airway eosinophilia,[60] there is a scope for both false positives and false negatives.[61] FeNO does not reliably identify non eosinophilic bronchitis which is also frequently seen in asthma.

The upper limit of normal of FeNO is widely variable (12.7 to 22.8 ppb in children, 24 to 54 ppb in adults).[62,63] Additionally, FeNO levels are affected by a number of other factors. It is often higher in atopic subjects,[64] higher levels with increasing age in children aged 17 years or less,[65] higher in males and lower in current smokers.[66] Fractional Concentration of Exhaled Nitric Oxide (FeNO) is increased by about 60% during the late allergic response in atopic asthma[67] and is reduced two to four fold by corticosteroids in asthma between three days to eight weeks.[68,69] A dose-response effect is observed with low-dose treatment but no additional benefit is seen above a budesonide dose of 400 mcg/day.[70]

Four studies have shown that a raised FeNO is predictive of loss of asthma control[71-74] but two other studies were less convincing.[75,76] Management strategies based on monitoring FeNO level resulted in lowering of ICS dose[77] and improved Airway Hyperresponsiveness (AHR).[78] However in contrast with the use of sputum cell counts to guide ICS treatment, exhaled nitric oxide was unable to reduce exacerbations in asthma patients.[79] Measurement of FeNO requires expensive equipment and is currently available in a few specialist laboratories. Although cheaper portable FeNO analyzers are now becoming available, there are concerns that absolute values may differ between different analyzers and stability over time needs to be established.[80,81] These factors may have implications in clinical practice.

Although there is some evidence that FeNO is useful in the diagnosis of asthma, in the prediction of asthma exacerbations and tailoring of asthma therapy, yet many ambiguities still remain. The variability of FeNO measurements in populations and within individuals needs to be more clearly defined, and specific cutoff points for FeNO values need to be more firmly established. Further studies are needed to address its exact role in guiding asthma management.

Key Recommendations for Clinical Practice

Noninvasive biomarkers of airway inflammation should be used to identify the bronchitic component of asthma that is otherwise not available to the clinician.

The only clinical comprehensive measurement currently available to assess airway inflammation is quantitative sputum cell counts.

It is imperative to introduce quantitative sputum cell counts in specialist practice to manage moderate to severe asthma.

Identification of eosinophils or neutrophils in the airway does not diagnose asthma. They help to predict the response to anti-inflammatory treatment and guide appropriate treatment.

In contrast to traditional clinical management, the use of induced sputum has been shown to be cost-effective in a specialist setting. FeNO measurements may be used as a surrogate marker for airway eosinophilia, may be used to predict response to corticosteroid therapy, low values may be of use to aid reduction in corticosteroid dose or to determine that ongoing respiratory symptoms are less likely to be due to eosinophilic airway inflammation.

Further studies with FeNO are needed to address outstanding questions about its exact role in guiding asthma management.

Exhaled Breath Condensate

A more recent noninvasive tool to assess airway inflammation is Exhaled Breath Condensate (EBC) measurements. The warm breath of subjects is collected on to cooled tubes so that the moisture condenses and the condensate can be collected. This condensate can then be analyzed for airway pH and various inflammatory markers (e.g. hydrogen peroxide, isoprostanes and cytokines).[20,82] Although the technique is noninvasive, allowing repeated samples to be collected and can be used even with small children, there are several unresolved problems with this methodology.[83] Currently the technique remains a promising research tool, with the potential for monitoring the inflammatory state in the airways and the effect of the novel therapeutic agents; however, more sensitive methods for measuring analytes and standardization of the collection methodology are needed.[20]

Measures of Allergic Status

Physicians commonly encounter patients with symptoms consistent with allergy. It can be difficult to determine which allergen is causing symptoms from the patient's history alone. Allergy tests yield information on sensitization, which is not always equivalent to clinical allergy; thus, interpretation in the context of clinical history is important. The two main allergy tests that are available to assist the physician to make an allergy diagnosis include the allergy skin tests and the measurements of allergen specific IgE (serum s-IgE) in addition to a thorough clinical history. However it is very important for the clinician to understand which allergy diagnostic tests to order, how to interpret the results of these tests and how to use the information obtained from the allergy evaluation to develop an appropriate treatment plan.

Medical History and Physical Examination

A history of allergic symptoms, seasonal variation, rapidity of onset and age of onset will help the clinician to determine if the patient's presentation is likely from an allergic cause. Physical examination findings such as allergic shiners, nasal crease, boggy nasal turbinates and pharyngeal cobblestones may further guide the physician.[84] If you suspect IgE-mediated allergic disease, always request and interpret skin tests and s-IgE tests in context of the clinical history. Positive test results provide objective confirmation of IgE sensitization, which will support a history of symptoms on exposure to a particular allergen. A negative test makes allergy to a suspected allergen unlikely. Avoid indiscriminate use of allergy tests as they may be commonly associated with false-positive results. Skin and serum IgE tests should never be used as a substitute for a careful clinical history.

Allergen skin tests: In clinical practice, the prick or puncture test is the preferred initial technique because it is relatively nontraumatic, elicits reproducible results when placed on specific areas such as arms or back and has better overall predictability. The reliability of prick/puncture tests depends on the skill of the tester, the test instrument, color of the skin, skin reactivity on the day of the test, potency and stability of test reagents. Sensitivity tends to be higher among pollens, certain foods, dust mite and fungi, compared with drugs and chemicals.[84,85] The number of skin tests and the allergens selected for skin testing should be determined from the patient's age, history, environment and living conditions, occupation and activities. A routine use of large number of skin tests without a definite clinical indication is not justified.[84]

Serum s-IgE: Multiple methods have been used to measure serum allergen s-IgE including Radioallergosorbent Test (RAST), Turbo RAST (Agilent Technologies Co, Santa Clara, California), Immulite (Siemens Medical Solutions Diagnostics, Tarrytown, New York), and ImmunoCAP (Phadia, Uppsala, Sweden). ImmunoCAP is the assay that has been most extensively studied.[86]

If the clinical history is positive and the serum s-IgE test result is negative, allergy skin testing should be considered. Serum s-IgE testing is preferred to prick or puncture testing when the patient has severe skin disease, is receiving medications that may suppress skin tests and cannot be removed from them, for uncooperative patients, or if the history suggests a risk of anaphylaxis from the testing.[84]

It is important in serum s-IgE tests and skin tests that results correlate with the history, physical examination findings, and in some cases timing of natural exposure to allergen. Therefore, it is often inappropriate to choose immunotherapy from remote laboratories based on history alone.

DIAGNOSTIC CHALLENGES

Preschool Children

Diagnosis of asthma in children aged 5 years and younger may be difficult because episodic respiratory symptoms such as wheezing and cough are also common in children who do not have asthma, particularly in those younger than 3 years.[87,88] It is further complicated by the difficulty in obtaining lung function in this age group. Alternative causes that can lead to respiratory symptoms of wheeze, cough and breathlessness must be excluded before making an asthma diagnosis. These include recurrent respiratory infections, allergic rhinitis, sinusitis, tuberculosis, foreign body in trachea or bronchus, vocal cord dysfunction, enlarged lymph nodes or tumor that may compress the large airways, recurrent aspiration due to dysfunction of swallowing reflex or gastroesophageal reflux and congenital problems such as tracheomalacia, tracheal stenosis, bronchostenosis, cystic fibrosis, bronchopulmonary dysplasia, congenital malformation of intrathoracic airways, primary ciliary dyskinesia syndrome, immune deficiency and congenital heart disease.[89]

Nevertheless, a diagnosis of asthma in young children can often be made based on symptom patterns, family history (first degree relatives, especially the mother) and physical findings. The presence of atopy (atopic dermatitis, food allergy, and/or allergic rhinitis) increases the likelihood that a wheezing child will have asthma.

It is important to avoid under diagnosing asthma, and thereby missing the opportunity to treat a child, by using such labels as “wheezy bronchitis,” “recurrent pneumonia,” or “reactive airway disease”.

Symptoms

Wheeze, cough, breathlessness and nocturnal symptoms/awakenings may indicate a diagnosis of asthma.

i. *Wheeze:* Not all wheezing indicates asthma. The ERS Task Group[90] has described two wheezing phenotypes (episodic wheeze and multiple trigger wheeze), whereas the US cohort study[91] has identified three wheezing phenotypes (transient wheeze, persistent wheeze, late-onset wheeze). The “episodic wheez” is the wheeze that occurs during discrete time periods, often in association with a common cold, with absence of wheeze between episodes. A “multiple trigger wheez” occurs as episodic exacerbations but also with symptoms including cough and wheeze occurring between these episodes, during sleep or with triggers such as activity, laughing, or crying. In “transient wheeze,” symptoms begin and end before the age of 3 years; in “persistent wheeze,” symptoms begin before the age of 3 years and continue beyond the age of 6 years; and in “late-onset wheeze,” symptoms begin after the age of 3 years. The clinical usefulness of these phenotypes remains a subject of much debate. Asthma occurs much more rarely in the episodic wheeze and transient wheeze phenotypes compared to the other phenotypes.

   Based on data from the Tucson (USA) Respiratory Study,[92] the Asthma Predictive Index (API) is recommended to predict the development of asthma in children with four or more wheezing episodes in a year.[93] A child with a positive API has a 4 to 10 fold greater chance of developing asthma between the ages of 6 and 13, while 95% of children with a negative API remained free of asthma.[93] The applicability and validation of the API in clinical practice is awaited.[89]

   Since many young children may wheeze with viral infections (respiratory syncytial virus and rhinovirus), it is challenging to differentiate whether the presence of wheeze with infections is truly an initial or recurrent clinical presentation of childhood asthma.[94]

ii. *Cough:* Cough due to asthma is recurrent and/or persistent, and is usually accompanied by some wheezing and breathing difficulties. Nocturnal cough or cough occurring with exercise, laughing or crying in the absence of an apparent respiratory infection, strongly supports a diagnosis of asthma.

iii. *Breathlessness:* Very often, parents describe this symptom as difficult breathing, heavy breathing or shortness of breath. Breathlessness that occurs during exercise, laughing and crying and is recurrent increases the likelihood of asthma.

Tests for Diagnosis and Monitoring

There is no test that will diagnose asthma with certainty in young children, but the following may be useful in making a diagnosis:[89]

i. *Therapeutic trial:* A marked clinical improvement in daytime and nocturnal symptoms and frequency of exacerbations during a trial of treatment with short-acting bronchodilators and inhaled glucocorticosteroids for at least 8 to 12 weeks and deterioration when it is stopped supports a diagnosis of asthma. A therapeutic trial may need to be repeated more than once to confirm the diagnosis of asthma.

ii. *Tests for atopy:* Sensitization to allergens can be assessed using either skin testing or antigen-specific IgE antibody. Skin prick testing is less reliable for confirming atopy in infants.

iii. *Chest radiograph:* If there is doubt about the diagnosis of asthma in a wheezing child, a plain chest radiograph may help to exclude infection (e.g. tuberculosis), congenital malformations of the airway such as congenital lobar emphysema or other diagnoses.

iv. *Other tests:* Lung function testing, bronchial challenge tests and other physiological tests do not have a major role in the diagnosis of asthma in children of 5 years and younger because children in this age group do not perform reproducible expiratory maneuvers. Such tests are only possible in specialized centers, and are undertaken mainly for research purposes.

v. *Exhaled nitric oxide:* High exhaled nitric oxide levels have been used to differentiate preschool wheezers with a high and low risk of developing asthma from preschool coughers.[95] However there is still no evidence to show whether exhaled nitric oxide levels can be used to differentiate persistent wheezers who are likely to develop asthma from other wheezy phenotypes.[89]

Older Children and Adults

In most cases, a careful history and physical examination together with the demonstration of reversible and variable airflow limitation by spirometry will confirm the diagnosis of asthma. Other causes of airway obstruction leading to wheeze should be considered both in the initial diagnosis and if the patient does not respond to initial therapy. These conditions may coexist with asthma or complicate the diagnosis and management of asthma. Common diagnostic challenges include the following:

Cough-Variant Asthma (CVA)

CVA is a distinct subset of asthma in which the main respiratory symptom is chronic cough associated with bronchial hyperresponsiveness and airway eosinophilia.[96] It can be encountered in both children and adults. In some patients, the cough may be associated with wheezing, chest tightness and various degrees of airflow obstruction, whereas in others cough could be the only presenting symptom with normal pulmonary function.[97] Higher sensitivities of cough reflex could explain the predominance in females.[98] In both adults and children, CVA may be a precursor of typical asthma; adults developed typical asthma after a period ranging from 1.5 to 9 years.[96] The predictors of progression to typical asthma include increased airway hyperresponsiveness,[99] eosinophilic airway inflammation,[100] blood eosinophilia,[101] longer duration of coughing,[102] age of onset[103] and no use of inhaled corticosteroids.[101,104] Typical asthma developed in 7.4% of patients taking inhaled corticosteroids and in 35.7% patients not taking inhaled corticosteroids.[101] Monitoring of PEF or bronchoprovocation may be helpful. Diagnosis is confirmed by a positive response to asthma medications.[96]

Vocal Cord Dysfunction (VCD)

Vocal cord dysfunction can mimic asthma, but it is a distinct disorder that is caused by abnormal adduction of the vocal cords during inspiration causing extrathoracic airway obstruction resulting in episodic dyspnea and wheeze.[105-106] In addition to severe asthma, VCD frequently occurs in mild-to-moderate asthma (72%).[106] Although physicians commonly refer patients with "classic" symptoms of stridor or hoarseness for VCD testing, a recent study[106] reports the lack of classic VCD symptoms among asthmatics. In fact, patients with both VCD and asthma present with nonspecific symptoms such as dyspnea, cough and wheeze, highlighting the need for a high index of suspicion for VCD in patients with asthma. The high prevalence of GERD (56.8%) raises the question of the role of acid reflux in the pathogenesis of VCD in asthmatics.[106]

Diagnosing vocal cord dysfunction requires a high index of suspicion. There is variable flattening of the inspiratory flow loop on spirometry; however a normal flow-volume loop should not influence the decision to perform a laryngoscopy.[107] Access to specialized Videolaryngostroboscopy (VLS) testing is required to definitively document VCD. The laryngeal movements during the entire procedure are digitally recorded. In order to be diagnosed as VCD, the patient must demonstrate abnormal constriction during the respiratory cycle and also normal complete abduction during some portion of the examination;[106] however false-negative tests can occur because VCD is paroxysmal.[105,108] Therefore, provocation with exercise or noxious stimuli is important to increase the likelihood of capturing an episode of VCD during VLS testing.[106]

It is yet unknown whether diagnosis and treatment of VCD has any impact on asthma control. Future prospective studies are needed to establish the impact of the diagnosis and treatment of VCD on asthma control.[106]

Gastroesophageal Reflux Disease (GERD)

Although 80% of asthmatic patients with positive pH probes have typical GERD symptoms such as heartburn,[109] approximately 40% have asymptomatic or silent GERD.[110]

GERD may induce asthma symptoms either by direct bronchospasm and increased airway hyperresponsiveness[111] or indirectly via microaspiration- induced airway inflammation.[112] Asthma patients have hyperinflated chests. Descent of the diaphragm in hyperinflated lungs increases the pressure gradient between the abdomen and chest and may cause the Lower Esophageal Sphincter (LES) to herniate into the chest where its barrier function is impaired.[113,114] Asthma medications such as beta 2-agonists and methylxanthine bronchodilators may decrease LES tone and may promote acid reflux.[113]

The use of pH probe findings is considered the most sensitive diagnostic test for GERD; however it does not reliably identify a subgroup of asthmatic patients who is likely to benefit from GERD treatment.[106]

Other Differential Diagnosis

Other differential diagnostic possibilities for asthma include congestive heart failure, pulmonary embolism, mechanical obstruction of the airways (benign and malignant tumors), pulmonary infiltration with eosinophilia, cough secondary to drugs [e.g. Angiotensin Converting Enzyme (ACE) inhibitors].[1]

Elderly

The diagnosis of asthma in the elderly is based mainly on clinical history and demonstration of reversible airflow obstruction with pulmonary function testing, but there are unique diagnostic challenges in older patients.

Medical History

Shortness of breath, chest tightness, usually dry cough, recurrent wheezing, nocturnal symptoms, worsening of disease at night, precipitation of symptoms following exposure to cold air, exercise or allergens support a diagnosis of asthma in the elderly.[115]

Pulmonary Function Testing

Many older patients will have difficulty in performing PFT. Performing PFT has been shown to be feasible in up to 88% of outpatients aged 65 and older.[116] Older adults may find it difficult to perform effective PFT because of the following reasons:[115]

- Inability to perform efficient forced expiration.
- Unable to follow instructions from the PFT technician because of cognitive impairment, sensory deficits (e.g. deafness, cataract) and/or impaired coordination (e.g. stroke).
- Poor post bronchodilator reversibility with beta 2-agonists.
- Fatigue and associated co-morbidities (e.g. cardiovascular disease).
- Mouth or dental problems (e.g. ulcers, dentures), which may affect the ability to hold onto the mouthpiece.

Difficulties Faced by a Clinician During Interpretation of PFT Reports

An obstructive pattern alone on spirometry in the absence of symptoms may reflect age-related pulmonary change such as decreased vital capacity, increased residual volume and functional residual capacity and not necessarily asthma.[117]

The predicted values of FEV_1 and FVC in normal elderly patients are based on data that is extrapolated from younger patients and therefore, tend to over predict values.[118] There is an accelerated decline in FEV_1 and FVC with advancing age, which is more rapid in men than women.[117] The clinician should consider these factors while making a diagnosis of asthma.

Age-dependent changes in pulmonary function and fixed obstruction (unchanged FEV_1 and FEV_1/FVC values pre- and postbronchodilator administration), which develops subsequent to airway remodeling makes it difficult for clinicians to differentiate between long-standing asthma and COPD.[119] Although bronchodilator reversibility will aid in distinguishing between asthma and COPD, a low Diffusion Capacity of Carbon Monoxide (DLCO) may tilt the diagnosis toward COPD and not asthma.[115] Beta-adrenergic dysfunction may be implicated in older patients.[120] Therefore, with the absence of a detectable change in the reversibility of airflow obstruction with SABAs, the test may be repeated with an anticholinergic agent. In some individuals, PFT does not demonstrate post bronchodilator reversibility, but an improvement is seen after systemic corticosteroid. The explanation of this phenomenon is based on the anti-inflammatory effect of corticosteroids. A two week trial of oral corticosteroid should be considered before repeating spirometry to detect an improvement in airflow obstruction which will aid in diagnosing asthma in difficult cases.[121] Nonetheless, asthma and COPD can both coexist in the same patient.[122]

Alternative Assessments

i. *Peak flow rates:* The use of peak flow variability to diagnose asthma in the elderly patients is not recommended because peak flow declines with age and peak flow variability becomes less reliable.[123] It is useful in detecting poorly controlled asthma, but it may not be fully reliable even in these circumstances.
ii. *Relaxed vital capacity:* Since older patients find it difficult to perform efficient forced expiratory maneuvers, a suitable alternative test is relaxed VC because it will be more discriminatory in older patients. The ratio of FEV:relaxed VC may be used to determine whether obstructive airway disease is present; however assessment of relaxed VC is more time consuming and requires technical expertise to perform the test correctly.[115]
iii. *Airway resistance:* As measurement of airway resistance or impedance using impulse oscillometry[124] and plethysmography[125] do not rely on maximal expiratory efforts, these methods have been proposed as a measure of airflow obstruction in older patients. Impulse oscillometry was successfully used to assess and quantify the airway obstruction in patients with dementia.[124] Further clinical studies need to address the validity and feasibility of these methods to assess airflow obstruction in the elderly.

Occupational Asthma

It is first necessary to establish a diagnosis of asthma in a patient and then identify Occupational Asthma (OA). A thorough medical history and objective work-related testing usually provides a reliable diagnosis of occupational asthma. A detailed history for suspected OA include chronological work history, job duties, exposures at work, onset and timing of symptoms, use of protective devices, presence of respiratory disease in coworkers, medication use and past lung function.[126]

The 2008 ACCP guidelines[127] recommend that the physician needs to address the following questions related to the onset and timing of the symptoms:

- Whether there were changes in work processes preceding the onset of symptoms
- Whether there was unusual exposure to sensitizers at work within 24 hours before the onset of symptoms
- Whether there is a temporal relationship of symptoms to periods while at and away from work (e.g. weekends, holidays)
- Whether symptoms of allergic rhinitis and /or conjunctivitis get worse with work

It would be very helpful to have up-to-date Material Safety Data Sheet (MSDS) in place for every chemical or material that may pose an occupational hazard for patients. MSDS contains information that will help to identify the suspect agent in the workplace.[128]

Objective Testing

i. *Peak expiratory flow rates:* Current guidelines[127] recommend that Peak Expiratory Flow Rates (PEFR) should be recorded at the workplace for a minimum period of four weeks including at least one week away from work. These PEFR readings should be performed in triplicate at least four times a day (e.g. preshift, midshift, postshift and bedtime, with similar times on days off work). Careful patient instruction is required because PEFRs are effort dependent. A typical pattern of OA is for patients to have better peak flow rates when they return to work after a weekend (e.g. on a Monday) or after holidays and get worse as the week progresses. Peak expiratory flow assessment has a sensitivity of 64 and 77% specificity.[129]
ii. *Airway hyper-responsiveness:* A methacholine or histamine challenge test should be performed at the end of a work week. The patient should remain away from work for at least 10 to 14 days, following which the challenge test should be repeated. A worsening of PC20 at work versus off work (greater than or equal to 4 fold change) further supports a diagnosis of OA.[127] A methacholine challenge test can revert to normal when a patient is away from occupational exposure.[130]
iii. *Specific inhalation challenge:* Specific Inhalation Challenge (SIC) exposes a worker to a specific suspect OA sensitizer in a controlled setting to demonstrate a direct relationship between exposure to the test agent and an asthmatic response. SIC may be associated with significant risk and should be performed in a specialized center under close supervision. This test is performed at limited centers in the world.[126]
iv. *Immunologic testing:* A negative skin test to a validated occupational protein allergen can reliably exclude occupational asthma.[127,131] Low Molecular Weight (LMW) sensitizers (e.g. metals, organic chemicals) may be associated with specific IgE antibody but limited *in vitro* tests are available for specific IgE to LMW agents and commercial tests have not been validated. Although these tests are not very sensitive, when positive they can support a diagnosis of OA.[132]

v. *Workplace challenge:* Workplace challenge testing is used when a specific agent cannot be identified as a potential cause for sensitizer induced OA or SIC is not available. The patient's spirometry is monitored at the workplace suspected to cause sensitizer induced OA.[133] For the purpose of comparison, the workplace challenge testing should be preceded by a control spirometry performed away from work.

vi. *Induced sputum cell counts:* Induced sputum analysis may assist in diagnosis of OA even before the development of respiratory symptoms and pulmonary function changes.[134] Although majority of subjects with OA show an eosinophilic airway inflammation after exposure to occupational agents during SIC,[135,136] neutrophilic inflammation has also been reported following exposure to isocyanates[137] and metal working fluid.[138] If there is an isolated increase in sputum eosinophil count of at least 2% without functional changes, the physician should pursue further investigation by increasing the duration of exposure to the suspected occupational agent.[139]

vii. *Exhaled nitric oxide:* There have been few studies examining work related changes of exhaled nitric oxide. Some studies have reported a higher exhaled nitric oxide in patients with OA[140,141] while others do not report a clear relationship.[142]

viii. *Exhaled breath condensate:* Exhaled breath condensate (EBC) collection is a noninvasive and repeatable tool to assess oxidative stress, acidification and inflammation in the airways.[143] The EBC concentration of hydrogen peroxide was increased in asymptomatic welders.[144] EBC pH was lower in welders exposed to cadmium, chromium, iron, lead, and nickel, than those exposed to aluminum and iron at the workplace. EBC analysis may be useful in occupational studies on a group level and in individuals who serve as their own controls. Based on methodological limitations, lack of standardization and difficulties in the interpretation of the data, EBC collection and analysis are primarily research tools and not yet suitable for implementation into clinical practice.[145]

Differential Diagnosis

Other conditions that may mimic occupational asthma include vocal cord dysfunction, upper respiratory tract infection, hypersensitivity pneumonitis, rhinosinusitis, byssinosis, popcorn worker's disease, flock worker's disease, eosinophilic bronchitis and psychogenic factors.[126]

Asthma and COPD

Guideline-recommended definitions for asthma and COPD are useful but limited because they do not fully depict the spectrum of obstructive airway disease that we see in clinical practice. There is a need to revaluate the concept of asthma and COPD as separate conditions. The various components of airway disease include symptoms, variable airflow limitation (asthma), chronic airflow limitation (COPD), airway hyper-responsiveness and airway inflammation. They can exist in various combinations, and bronchitis or airway inflammation is the central component. When considered in this way, asthma and COPD are physiological components of airway disease and bronchitis is the inflammatory component.[146] An asthma patient may or may not have eosinophilic bronchitis, COPD can occur in a nonsmoker. A smoker with COPD may have an eosinophilic bronchitis. A neutrophilic bronchitis can occur in asthma or COPD. Hence the diseases are not mutually exclusive and can overlap (overlap syndrome). Combinations commonly occur and can vary from one patient to another.

Why is the Overlap Syndrome Important?

With increasing age, there is a greater increase in the proportion of patients (55%) with the overlap syndrome and fewer (19%) older patients have the classical phenotypes of emphysema alone or chronic bronchitis alone.[147]

Patients with the overlap syndrome are excluded from randomized controlled clinical trials and therefore, data on the efficacy of treatment may not be relevant in this population.[148] Studies on the efficacy of inhaled corticosteroids in asthma excluded smokers with asthma despite the fact that up to 32% of asthma patients are smokers.[149] As a result extrapolation of efficacy results for corticosteroids in nonsmokers to smokers with asthma is flawed and we know that smokers with asthma have a relative corticosteroid resistance.[150] Overlap syndrome of asthma and COPD need to be included in drug evaluation programs.

Clinicians are often confused as to how to differentiate between asthma and COPD and use extended nonuniform diagnostic labels for obstructive airway disease (e.g. asthma with chronic bronchitis, asthmatic bronchitis).[151] Recognition of the overlap syndrome may help identify shared risk factors such as increasing age and smoking,[152] bronchial hyper-responsiveness[153] and exacerbations,[154] which will help to understand and modify the accelerated decline in lung function that leads to COPD.

Clinical Recognition of the Overlap Syndrome

The clinical recognition of both asthma and COPD requires assessment of symptoms and physiological function abnormalities.[148] Patients with asthma, COPD and overlap syndrome can all present with symptoms; however there is a difference in the physiological function abnormalities. Patients with the overlap syndrome have incomplete reversible airflow obstruction [$FEV_1/FVC < 70\%$, $FEV_1\%$ Pred (post bronchodilator) < 80%] but also have increased bronchial hyperresponsiveness (PD_{15} of hypertonic saline that induces a 15% fall in FEV_1 is less than 12 ml).

Patient groups that have features of both asthma and COPD include smokers with asthma, asthma patients who develop COPD and nonsmokers who develop COPD.[148] Long-standing asthma patients who develop COPD tend to be older (44 years), more often males and have a long duration of disease (25 years).[155,156] Sixteen percent of patients with asthma developed COPD after 21 to 33 years of follow-up.[157] In a recent study[148] only 16% and 21% patients could be reported definitely as asthma and COPD respectively. Majority (65%) of the patients had the overlap syndrome of asthma and COPD. The rate of atopy was intermediate (64%) in the overlap syndrome. Airway complications resembled COPD rather than asthma.

Inflammatory Features of the Overlap Syndrome

The pattern of airway inflammation associated with both asthma and COPD is heterogeneous but is more likely to resemble COPD rather than asthma with increased sputum neutrophils. Smokers with asthma are less likely to have eosinophilic inflammation[158] and more likely to have airway neutrophilia.[159] In our retrospective survey of 2,443 patients with airway disease,[42] 9% had asthma with COPD. In stable disease, eosinophilic bronchitis was more frequently seen (35%) whereas neutrophilic inflammation was more common during exacerbations (33%). Induced sputum biomarkers such as IL-12, IL-13 and IFN-gamma were predominant in patients with both asthma and COPD, whereas IL-9, IL-17, monocyte chemotactic protein 1, and Regulated Upon Activation, Normal T Cell Expressed And Secreted (RANTES) were dominant in those with asthma without chronic airflow obstruction.[160]

Airway Remodeling in Overlap Syndrome

Subjects with severe asthma and chronic persistent obstruction have increased airway smooth muscle (15.65%) versus that (8.96%) seen in patients without chronic airflow obstruction; however airway measurements on high-resolution computed tomographic scans revealed no differences between the groups.[160]

The overlap syndrome of asthma and COPD is supported by the Dutch Hypothesis,[161] which states that the different types of airway diseases should not be considered as separate conditions but as one disease entity with different components. The presence of different components (asthma, COPD) is influenced by host and environmental factors. We need to evaluate the components of the disease in order to individualize and optimize treatment to achieve the best effect with the least side effects and cost to the patient.

CONCLUSION

The clinical diagnosis of asthma is usually based on an accurate medical history, supported by physical examination and demonstration of variable airflow obstruction. This would involve demonstration of bronchodilator reversibility in patients with baseline airflow obstruction or bronchial hyperresponsiveness in patients without baseline airflow obstruction. An alternative would be demonstration of natural variability in airflow obstruction using home peak flow recording. Although this is less sensitive than demonstration of bronchial hyperresponsiveness to diagnose asthma, new statistical methods to analyze peak flow recording such as autocorrelation and coefficient of variation of measurements[162] may prove increasingly useful. Objective assessment of airway inflammation especially quantitative sputum cell counts need to be implemented into specialist practice to identify the bronchitis component of asthma. They do not help to diagnose asthma. A referral to a specialist centre that has expertise to perform bronchial provocation tests, evaluation of allergy and measurement of airway Inflammometry is appropriate in patients with uncertain diagnosis, particularly, those who do not seem to improve with conventional treatment for asthma.

Airway Inflammation and Remodeling

Ruby Pawankar, Shu Hashimoto, Bassam Mahboub

INTRODUCTION

Both Allergic Rhinitis (AR) and asthma may factually be considered as one single disease, based on the unifying concept of "One airway – One disease." Allergic rhinitis is a chronic inflammation of the nose, characterized by symptoms of sneezing, rhinorrhea, nasal itching and nasal obstruction. Asthma is a chronic, inflammatory condition of the lower airways characterized by largely reversible airflow obstruction, airway hyperresponsiveness, and episodic respiratory symptoms, including wheezing, productive cough, and sensations of breathlessness and chest tightness.[1]

Clinically, AR is an Immunoglobulin E (IgE)-mediated, T helper cell 2-type (Th2-type) inflammatory disease whereas asthma may be divided into allergic and non-allergic asthma, distinguished by the presence or absence of IgE antibodies to common environmental allergens. About 80% of childhood and 50% of adult asthma is allergic (i.e. IgE associated). In the latter, the triggers are not well known, but are probably microbes or microbial components. However, both forms of asthma are characterized by Th2-type inflammation, stimulation of inflammatory cells, like mast cells, causing eosinophilia, leukocytosis, and enhanced B-cell IgE production, leading to airway hyperresponsiveness and tissue remodeling. The determinants for an individual to develop an asthmatic phenotype require both exposure to appropriate stimuli and a genetic predisposition.[2,3]

Airway remodeling involves structural changes in the airway wall characterized by epithelial alterations (epithelial shedding or denudation as a result of toxic proteins released especially by eosinophils), goblet cell metaplasia (their numbers increase first), bronchial mucus gland enlargement (excess production of mucus), subepithelial fibrosis and extracellular matrix deposition, increased smooth muscle mass and increased vascularization.[2] Chronic inflammation causes tissue injury, which is partly repaired between inflammatory exacerbations. Airway remodeling is associated with poorly-reversible or nonreversible airway narrowing, more severe airflow limitation and airway hyperresponsiveness and may be involved in component of adult severe asthma.[4] These changes involve both large and small airways, but the individual variation is large. Airway secretions also contribute to the airflow limitation in asthma, and increase in amount and viscosity of the secretions plays a crucial role especially in acute, life-threatening exacerbations.[5] However, based on current knowledge the characteristic structural changes seen in remodeling is not a feature of AR.

Although much more is known in terms of the inflammatory mechanisms underlying AR and asthma, there is still a gap in our understanding of the cellular and molecular pathways involved in remodeling. Both inflammation and remodeling occur in the tracheobronchial tree of patients with asthma. Persistent, eosinophilic inflammation seems to be a prerequisite for the development of remodeling.[6] Increased vascularity and expression of Vascular Endothelial Growth Factor (VEGF) are features of the asthmatic airway, but little is known about their contribution to airway remodeling. Siddiqui et al.[7] showed that vascular remodeling is a feature of asthma, and is inversely correlated with postbronchodilator Forced Expiratory Volume in One Second (FEV_1) indicating a role in airflow obstruction.

Until recently, airway remodeling was considered to be a secondary phenomenon, developing later in the disease process as a consequence of persistent inflammation. The presence of airway inflammation and remodeling in children[8] with asthma indicates that the process of remodeling begins early in the disease process of asthma and synchronously with ongoing and repeated airway inflammation rather than as a consequence of airway inflammation. Structural changes of the airways are already present and maximal in severely asthmatic school children,[9] indicating the changes begin early in life between the ages of 1 and 3 years; and in good association with tissue eosinophilia and reticular basement membrane thickening.[10] This gives a window of opportunity for early intervention that can possibly modify the natural history of asthma.[11]

CHRONIC INFLAMMATION IN AR AND ASTHMA (FIGS 67.1 AND 67.2)

The Inflammatory Response

The upper and lower airways have a similar mucosal structure, and exhibit similar inflammatory reactions to irritants and allergens. Increasing evidence indicates that there is marked similarity in the degree of cell infiltration or cytokine expression during allergic inflammation between the nasal mucosa and bronchial mucosa.[12,13] However, there are minimal structural changes of the nasal mucosa in AR unlike that in asthma.

In allergic asthma and AR, inhaled allergens penetrate the mucociliary lining and enter the airway epithelium either via the tight junctions that surround the apical zone of epithelial cells or by direct uptake by the cells per se. Allergens are presented to T-cells that then react by forming a pool of Th2 (IL-4, IL-5 and IL-13 secreting T-cells) that drive the production of IgE via interaction with B-cells. Subsequently, the IgE binds to the high affinity IgE receptor on mast cells, and cross-linking of allergen specific IgE on the surface of mast cells by allergens causes the activation of mast cells and the release of mediators such as histamine and leukotrienes. They increase vascular permeability and initiate a cascade of recruitment of more inflammatory cells and further release of proinflammatory mediators.

Effector Cells of Inflammation

Mast Cells and Basophils

Mast cells are critical in mediating the early phase of inflammatory response in AR and asthma. However, more recently it is known that mast cells are not only effector cells of the immediate phase response, but also play a role in on-going allergic inflammation. They store and produce Th2-type cytokines, chemokines, induce IgE synthesis in B cells,[14,15] express the $CysLT_1$ receptor,[16]

GR receptor,[17] and SAF-2,[18] and upregulate the production of cytokines/chemokines in epithelial cells and fibroblasts.[19]

Accumulation of mast cells into the nasal and bronchial epithelium, a feature of AR and atopic asthma is also reported in idiopathic rhinitis.[20] Regulated Upon Activation, Normal T-Cell Expressed and Secreted (RANTES) and TGF-β are implicated in the intraepithelial migration of mast cells.[19,21] Increase in mast cells and basophils occur within one hour of Nasal Allergen Challenge (NAC).[22] Patients with AR with or without asthma have similar number of intraepithelial mast cells,[23] and Segmental Bronchial Challenge (SBC) induces an increase in basophils and eosinophils predominate in nasal and Bronchoalveolar Lavage (BAL).[24-27]

Airway mast cells stimulated via the FcεRI are an important source of Th2 cytokines, proinflammatory cytokines like TNF-α (preformed in mast cells) and chemokines like Thymus And Activation-Regulated Chemokine (TARC), as well as the IL-7 like cytokine Thymic Stromal Lymphopoietin (TSLP).[28,29] FcεRI-mediated TSLP production from mast cells is further enhanced in an autocrine manner by IL-4.[30] Moreover, mast cells can interact with structural cells, like epithelial cells to enhance the production of cytokines and chemokines from epithelial cells. TNF-α in concert with IL-4 and IL-13 enhances the production of TARC, TSLP and eotaxin from epithelial cells.[19] These result in increased infiltration of Th2 cells, eosinophils and differentiation of dendritic cells. Moreover, tryptase and chymase from mast cells can upregulate RANTES and GMCSF production from epithelial cells.[19] TNF-α also promotes antigen and Th17 cell-dependent neutrophilia after allergenic stimulation and induces dendritic cell migration.[31,32] Murine mast cells have been shown to induce CD4$^+$T-cell migration *in vitro*, but down-regulate FcεRI expression in T regulatory (T reg) cells, while activated T reg cells suppress mast cell FcεRI expression.

Mast cells can induce IgE synthesis in B-cells and local IgE synthesis has been demonstrated in the nasal mucosa of patients with AR.[33,34] IL-4 and IgE upregulate *FcεR*I expression in mast cells suggesting a crucial role for the mast cell-IgE-IgE receptor cascade in on-going inflammation in AR and asthma.[34] A role for mast cells in antigen presentation is also suggested.[35]

While classically, mast cell activation occurs following the allergen crosslinking of *FcεR*I-bound, allergen-specific IgE, they may also be activated through multiple other mechanisms, like via the complement receptors, FcγRI and via TLRs even in the absence of FcεRI stimulation.[36-40]

Basophils are increased in the nasal secretions and BAL of patients with AR and asthma. Like mast cells, basophils can also initiate allergic inflammation through the binding of allergen-specific IgE antibodies to the FcεR1 on basophil cell surface.[41] Basophils also drive Th2 cell differentiation of activated naive CD4$^+$T cells via production of IL-4 and direct cell-cell contact.[42] Basophils in AR and atopic asthmatics also express high levels of the *FcεR*I.[43] Downregulation of *FcεR*I in basophils and mast cells comprises one of the target mechanisms of the efficacy of anti-IgE monoclonal antibody (Omalizumab).

Eosinophils

Eosinophils increase in both the early and late phase of AR[44] and correlate with nasal flow, IL-4, IL-5, IL-8 and IFN-γ, spirometric values, methacholine test positivity, percentage of predicted FEV_1 and Bronchial Hyperreactivity (BHR).[45-54] Eosinophils are increased in symptomatic ectopics and increase in nasal, as well as bronchial epithelium and lamina propria after NAC.[22,55-57] Eosinophils are a major source of Migration Inhibitory Factor (MIF)[58] and Nerve Growth Factor (NGF),[59] express 5-LO, FLAP and LTC_4S, and $CysLT_1$ and $CysLT_2$ receptors,[60] are involved in the loss of epithelial integrity[61] and are also seen in the esophageal mucosa of symptomatic patients with respiratory allergy.[62]

Interleukin-5 has a key role modulating eosinophil differentiation and survival. Targeting IL-5 as a therapeutic strategy for allergic asthma with anti-IL-5 therapy has demonstrated marked reduction of peripheral blood eosinophils, but only partial abrogation of the pulmonary eosinophilic response and with minimal impact on clinical outcomes.[63,64] More recently, in selected patients with refractory, eosinophilic asthma anti-IL-5 monoclonal antibody (mepolizumab) reduced both peripheral blood and sputum eosinophil levels, asthma exacerbations, and resulted in a reduction in oral corticosteroid dose.[65,66]

Eosinophil chemoattractants include eotaxin, Macrophage/Monocyte Chemotactic Protein-4 (MCP4), RANTES, and cysteinyl leukotrienes (cysLTs) among others.[67,68] They act on distinct cell surface receptors [e.g. CC chemokine receptor 3 (CCR3) and $cysLT_1$] present on the eosinophil, but not exclusively so. Challenge with leukotriene E_4 (LTE_4) or leukotriene D_4 (LTD_4) results in increased nasal secretion and nasal obstruction in AR and greatly increased numbers of eosinophils in the bronchial wall.[67,68] $CysLT_1$ receptor is expressed on a variety of nasal and bronchial inflammatory cells, including eosinophils, neutrophils, mast cells, macrophages, B lymphocytes and plasma cells.[69] These numbers of inflammatory cells expressing the $cysLT_1$ receptor are also increased in AR and asthma and there is a further, significant increase among patients experiencing a severe exacerbation of asthma leading to hospitalization.[70]

Activated eosinophils release highly toxic granules, the evolutionary function of which has probably been killing the potentially dangerous invader. Especially in asthma, eosinophil derivatives damage the surface epithelial cells, loosening their attachments and resulting in the shedding of cells into the airway lumen, where they admix with eosinophils, neutrophils and mucus.

T Lymphocytes

In PAR patients, $CD3^+$, $CD25^+$ (activated) and $CD45RA^+$ (naïve) T-lymphocytes are increased in the nasal mucosa. In PAR, Memory T-cells and in idiopathic rhinitis, CD8+ T-cells correlate with mucosal mast cells.[71] While CD86 is expressed on CD19; CD1a, CD14 and CD3 T-cells in PAR; CD80, CD28 and CD152 are expressed after NAC.[72] Moreover, CCR4+ CD4 cells are increased in AR.[73] Besides, Th2 cytokines and chemokines, T-cells in AR express IL-16,[74] CXCR1[75] and CX(3)CR(1).[76] Mucosal δγ T-cells in PAR and asthma are increased, induce IgE synthesis in B-cells and induce proliferation of αβ T-cells.[77] $CD23^+$ B-cells increase in PAR, but do not correlate with the mucosal Th2 cells.[73]

Although conventionally, both AR and allergic asthma have been considered to be due to a disruption in the normal Th1/Th2 balance, more recently, there is new evidence on the emerging roles of Th17 cells, which are a distinct subpopulation of CD4+ T-cells that produce IL-17A, IL-17F, IL-22, TNF-α, and IL-21.[78] Th17 cells were found in the nasal mucosa of AR patients[79] and in bronchial biopsies of asthmatics.[80] IL-17 induces the release of proinflammatory cytokines/chemokines from a variety of cell types,[79] is linked to the development of airway neutrophilia, and its presence in the asthmatic airway, correlates with increased severity of disease. T reg cells play roles in the determination of self tolerance and the regulation of immune responses. Th17 and T reg cells have opposing actions, and T reg cells secrete IL-10 and TGF-β and are increased in patients after immunotherapy.

Neutrophils

Although neutrophils are predominantly increased in nonallergic infective rhinitis and chronic rhinosinusitis, the increased expression of activation markers on neutrophils and Myeloperoxidase (MPO) levels in AR and increase in neutrophils in BAL after NAC suggests roles for neutrophils in AR.[25,81] In acute, severe exacerbations of asthma, there are increased eosinophils and neutrophils within the airway, and the increase in neutrophils is proportionately greater.[82] Inhaled corticosteroids reduce airway eosinophils, but increase airway neutrophils and neutrophil chemoattractant IL-8, with loss of asthma control.[83]

Epithelial Cells

Conventionally, epithelial cells placed at the interface between the external environment and the host have been considered to play a role as a defense barrier against environmental agents. However, over the past several years, the roles of epithelial cells as effector cells has become more evident, directly via the action of inflammatory mediators, as well as via cell-cell interaction with immune cells. Moreover, its pivotal position in orchestrating airway remodeling and fibroblast proliferation is also crucial.[84]

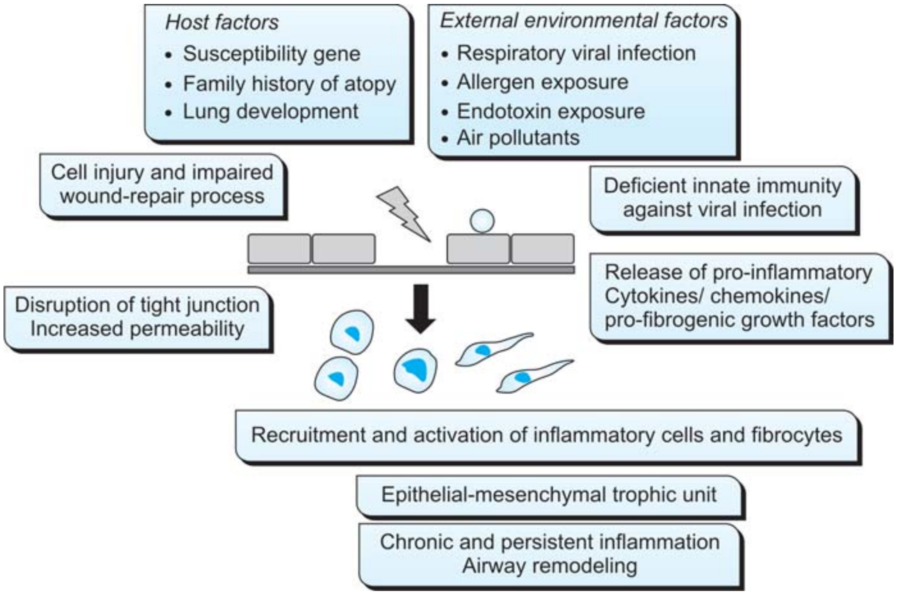
Airway epithelial cells are an important source of a variety of inflammatory mediators, including multifunctional cytokines and chemokines like IL-1, IL-6, IL-8, TNF-α, GMCSF, RANTES, Eotaxin and TARC, leading to their crucial role in the migration and activation of immune cells like eosinophils, basophils and Th2 cells.[85,86] More recently, TSLP derived from epithelial cells is increased in the nasal mucosa of AR patients and in the asthmatic airway.[87] TSLP can activate dendritic cells, promote Th2 responses and activate mast cells.[30] Epithelial cells also express costimulatory molecules like CD86 and HLA-DR, CD86 and the FcεRI can present antigen to T-cells.[88,89] Particulate matter like DEP can induce the release of proinflammatory mediators and enhance the expression of costimulatory molecules on epithelial cells.

Minimal Persistent Inflammation

Even when symptoms are absent in chronic inflammatory diseases like AR and asthma, a minimal level of persistent inflammation may persist and, to prevent unexpected exacerbations, the treatment strategy may need to include its management. Immunotherapy and antihistamines reduce persistent inflammation by decreasing ICAM-1 expression in epithelial cells and eosinophil cationic protein in patients with mite-induced AR.

REMODELING IN ASTHMA (FIG. 67.3)

Remodeling is defined as a change in structure that is inappropriate to maintain the normal airway function.[90,91] Some features of remodeling are evident, even in newly diagnosed or mild asthmatics and is characterized by epithelial fragility and reticular basement membrane thickening. With increasing severity of asthma, the changes are more pronounced and clear: Increase of airway smooth muscle mass, vascularity, numbers of fibroblasts, and interstitial collagen, as well as mucus gland hypertrophy.[92] These changes appear to be the greatest in the larger, more proximal airways. Thickening of the reticular basement membrane occurs early in asthma, even before diagnosis, and is detected



Host factors
• Susceptibility gene
• Family history of atopy
• Lung development

Chronic and persistent inflammation Airway remodeling

Fig. 67.3: Airway inflammation and remodelling in asthma [Modified from Hashimoto et al ACII. 2002]

in children with mild asthma.[93] In school children between the ages of 6 and 16 with severe asthma there is already maximally thickening, but with no relation to the age or symptom duration.[9] These changes appear in preschool wheezy children by the age of 29 months.[7] Bourdon et al.[94] showed recently, that reticular basement thickness is a hallmark of severe asthma, but not of mild asthma or Chronic Obstructive Pulmonary Disease (COPD).

Airway smooth muscle surrounds the airways as two opposing helices, i.e. a geodesic pattern and as muscle shortens, it constricts and also tends to shorten the airway against an elastic load. Airway smooth muscle mass is increased in the asthmatic airway.[95] Airway smooth muscle cells can secrete mediators that may promote mast cell chemotaxis, proliferation and survival, while cell-cell interaction between airway smooth muscle cells and mast cells enhances activated complement-induced mast cell degranulation.[96-98] Human lung mast cells migrate towards Th2 cytokine-stimulated airway smooth muscle cells from asthmatics, while supernatants obtained from airway smooth muscle cell cultures of non-asthmatics inhibit this chemotaxis.[99] Large numbers of mast cells have been found located within the bronchial smooth muscle of asthmatics and mast cell mediators, such as tryptase and cytokines can modulate airway smooth muscle cell function. Mast cells also express MMP-9 and contribute to multiple features of chronic asthma tissue remodeling.[19]

Bronchial epithelial cell experiments have demonstrated a role for TLR signaling in the activation of epidermal growth factor receptor, suggesting a role for TLRs in potentiating remodeling.[100] In the asthmatic airway, there are increased numbers of subepithelial myofibroblasts, and allergen challenge in people with asthma leads to the increased accumulation of myofibroblasts in the airway mucosa.[84,101]

Histamine can induce the transition from fibroblasts to myofibroblasts (as measured by α–smooth muscle actin expression), and induce connective tissue growth factor expression in fibroblasts, suggesting the ability to participate in the process of remodeling.[101,102] Fibroblastic infiltration of the lung may be secondary to the recruitment of circulating bone marrow-derived progenitors of fibrocytes to the airway and to the proliferation and expansion of resident fibroblasts, or possibly, epithelial cells may undergo phenotypic change to effector fibroblasts through a process termed Epithelial-Mesenchymal Transition (EMT).

Airway epithelial cells derived from asthmatics demonstrated increased susceptibility to TGFβ-induced EMT than those derived from normal subjects.[103] In addition to the stimulation of epithelial cells and ECM synthesis, TGFβ can elicit other responses in bronchial fibroblasts, including stimulating their proliferation and synthesis of a range of growth factors. It also has effects on the asthma susceptibility gene, a disintegrin and metalloprotease 33 (ADAM33), which has been implicated as an asthma remodeling gene.

Measuring airway function (e.g. FEV_1) can give indirect information on the long-term airway inflammation and structural changes, but cannot detect the early inflammatory processes. Such inflammatory changes can exist even in patients with normal lung function, but with symptoms indicative of asthma.[104] On the other hand, symptomatic infants, who have reversible airflow obstruction may not have bronchial mucosal eosinophilia or remodeling.[8]

How Early Can Remodeling Start?

Airway biopsy studies in children suggest that pathological changes, such as epithelial loss, basement membrane thickening and angiogenesis occur early in the asthmatic airway. In children with difficult asthma (mean age of 13, age range of 6–16) recruited to investigate whether the thickening of reticular basement membrane could occur in the childhood asthma[9] have shown that the thickening of reticular basement membrane was seen in the airway. Barbato A et al. had examined the biopsy specimens of airway in nine children with asthma (age of 4–12 years), six children with atopy without asthma (age of 4–12 years), and in eight control children without asthma or atopy to elucidate whether airway inflammation and remodeling could occur even in mild childhood asthma.[92] It was nicely demonstrated that airway eosinophilia and basement membrane thickness were present in children with mild asthma, and even in children with atopy without asthma. This indicates the following:

- Airway inflammation shown by airway eosinophilia occurs even in mild as well as in difficult asthma
- Airway inflammation occurs in the airway before developing episodic wheezing, although asthma symptom is difficult to establish in children
- The presence of both airway inflammation and remodeling indicates that remodeling process begins early in the disease process of asthma and occurs synchronously in ongoing and repeated airway inflammation rather than as a subsequent event of airway inflammation.

Update on Therapy for Airway Remodeling

Current advances in our understanding of the treatment for airway remodeling highlight that though the remodeled asthmatic airway cannot be fully reversed, targeting therapy towards reducing the risk of developing airway remodeling is crucial. Myofibroblasts are key cells that play a crucial role in the process of remodeling via the synthesis of collagen. Therefore, targeting myofibroblasts can be useful. Recently, it was reported that the combination of Inhaled Corticosteroids (ICS) with Long-acting beta2-Agonists (LABA) reduced the allergen-induced increase in airway myofibroblasts as well as airway eosinophilia as compared with inhaled corticosteroids alone, indicating that the combination of ICS with LABA is superior for reducing airway inflammation and the risk of developing airway remodeling.[105] For difficult-to-control asthma or severe corticosteroid-refractory asthma, an immunomodulator like the anti-IgE mAb (Omalizumab) is recommended. Bronchial thermoplasty is another novel and potentially effective therapy with growing evidence on its clinical effectiveness. However, more evidence is needed on the long-term benefits of thermoplasty.[106]

SUMMARY

The development of AR and asthma requires an interaction between the environment, immune system and genetic susceptibility. While pollen-induced rhinitis is the most characteristic IgE-mediated allergic disease; in perennial allergic rhinitis the allergic triggers are more continuous and lead to an on-going inflammation. Several cells and mediators orchestrate and maintain this inflammation. Although histamine is still one of the major mediators of the allergic reaction, many other mediators produced by different cell types are involved. Thus, the intricate interaction amongst these mediators, cytokines, chemokines, neuropeptides, adhesion molecules and various cells in the form of a complex network leads to the development of specific symptoms and the nonspecific hyperreactivity of allergic rhinitis.

Asthma is characterized by variable degrees of chronic inflammation and structural alterations in the airways, which include epithelial denudation, goblet cell metaplasia, subepithelial thickening, increased airway smooth muscle mass, bronchial gland enlargement, angiogenesis, and alterations in extracellular matrix components, involving large and small airways. Chronic inflammation is thought to initiate and perpetuate cycles of tissue injury and repair in asthma, although remodeling may also occur in parallel with inflammation. While AR and asthma share several similarities in the inflammatory cell and mediator profiles and responses, remodeling as seen in asthma is not characteristic of AR. In asthma, the relationships of airway inflammation, remodeling and lung function are becoming better understood. A variety of inflammatory cells and structural cells play a role in orchestrating the inflammation and structural changes in asthma. Increased airway responsiveness is a surrogate marker of inflammation and may reflect the development of structural changes in the airways. Such persistent increased bronchial responsiveness indicates remodeling, which is partly resistant to therapy.

Moreover, with the increasing evidence on the links between allergic rhinitis and asthma from epidemiological, immunological and clinical studies, early intervention and downregulation of inflammation are the keys to better control of both AR and asthma. New modes of immunomodulatory therapies are under trials or at different stages of development for both AR and asthma. Anti-IgE and anti-Tumor Necrosis Factor (TNF) alpha therapies hold more promising outcomes, but their effect on halting airway remodeling in severe asthma is not known. Given the similarity that exists between the patterns of inflammation in asthma and allergic rhinitis and the impact of AR on asthma, treatment should focus to have a global approach to treat both the upper and lower airways for better outcomes.

Control and Management of Stable Asthma

Sidney S Braman, David Lee

INTRODUCTION

Treatment protocols for the management of stable asthma have undergone considerable change over the past 50 years. During the mid 20th century, an effort was made to improve the currently available bronchodilator medications. Selective, inhaled short-acting adrenoceptor agonists became available in 1969. They offered fewer cardiostimulatory effects than were experienced with commonly used drugs like racemic epinephrine and isoproterenol. Beta-agonist agents with more potency and a longer duration of action were produced, at times with disastrous results that lead to epidemics of asthma mortality.[1] Ephedrine, a drug used for centuries as a Chinese herbal remedy, Ma Huang, was eliminated in some countries as an asthma treatment because of the potential for cardiovascular and CNS stimulatory effects and the use as a recreational drug. Anhydrous theophylline, another bronchodilator, was the mainstay of asthma treatment, although it was fraught with side effects and drug-drug interactions that lead to significant toxicity and mortality. While its use has declined in the recent years, theophylline still plays a role in asthma care as a third or fourth-line agent and when less expensive alternatives are required. In the past years, agents were used to reduce the "anxiety" of asthma, such as phenobarbital and hydroxyzine, but this practice is no longer advised. The end of the 20th century introduced a dramatic new approach to asthma care as the disease became recognized as a chronic inflammatory disease of the airways. In susceptible individuals, it was inflammation that caused the recurring symptoms.

While sudden, unexpected asthma symptoms can be relieved with "rescue" inhaled bronchodilator treatment, the long-term goal of asthma treatment is directed at reducing and possibly eliminating airway inflammation. Medications labeled "controller therapy" are used for this purpose. In 1974, inhaled glucocorticoids became available to treat asthma and since that time, they have become the mainstay of controller therapy for persistent asthma symptoms. It is also recognized that proinflammatory mediators called leukotrienes are important in the pathogenesis of asthma. Agents that are capable of inhibiting the synthesis or action of leukotrienes were introduced in the 1990s as controller treatment for asthma.

With new insights into the pathogenesis of asthma, and advent of newer and safer medications to control the disease, there is reason for optimism in the management of asthma. A global strategy through international asthma guidelines has provided a roadmap for asthma care, including the goals of treatment and evidence-based protocols to lead clinicians to successful outcomes for their patients.[2-5]

THE GOALS OF ASTHMA TREATMENT

There are both short- and long-term therapeutic objectives for every asthmatic patient (Table 68.1). The short-term objectives are to control immediate symptoms and respond to falling lung function measurements (peak flow rates, spirometry). Long-term objectives are those directed at disease prevention, since there are now well-proven strategies to avoid serious exacerbations of acute bronchospasm that may lead to emergency care,

TABLE 68.1: Goals of asthma treatment

1. Limit symptoms of dyspnea, wheeze, chest tightness and cough; day and night
2. Provide normal daily activity level; no absenteeism from work or school
3. Maintain normal or near-normal lung function
4. Reduce or eliminate asthma exacerbations; avoid emergency visits and hospitalizations
5. Minimize the use of rescue medication and use lowest dose and fewest medications possible
6. Avoid side effects of medications

hospitalization and asthma mortality. In order to meet these therapeutic objectives, four components of asthma care should be addressed (Table 68.2). First, measures should be taken to avoid exposure to respiratory allergens and irritants, or other "triggers" of asthma that can cause the worsening of symptoms (Fig. 68.1). This includes the avoidance of outdoor and indoor allergens and irritants that can be found in the household or work environment and treatment of asthma comorbidities such as gastroesophageal reflux. Second, the optimal management of asthma depends on a careful assessment of the patient's symptoms, including the use of objective measures of asthma control with questionnaires and physiological testing. Third, the treatment of asthma with bronchodilator and anti-inflammatory medications is tailored to the patient's needs in a step-up and step-down manner. This approach begins with a staging system that is based on the patient's symptoms and objective measures of lung function and relies on an assessment of the control of asthma symptoms for ongoing care. Fourth, patient education can be a powerful tool in asthma control. Family members can be helpful, especially with children and elderly adults. Active participation by a patient in monitoring lung function, avoiding provocative agents, and making decisions regarding therapy provide asthma management skills that give that patient the confidence to control his or her own disease.

TABLE 68.2: Essential components of successful asthma care

Avoidance: Eliminate asthma "triggers", such as allergen exposure and home/workplace irritants

Monitoring: Use of self-assessment questionnaires, peak flow measures, spirometry

Treatment: Anti-inflammatory therapy is the foundation of successful treatment for persistent asthma; short-acting bronchodilators for rescue from sudden symptoms

Patient education: Provide the necessary tools for self-management, including an action plan for exacerbation of symptoms

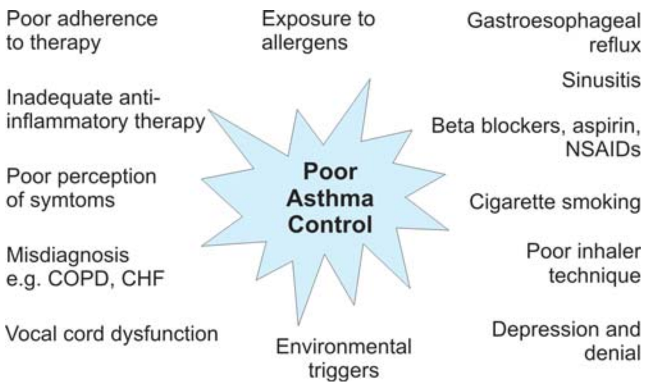

Fig. 68.1: Causes of poor control of asthma

ESSENTIAL COMPONENTS OF ASTHMA CARE

Avoidance

In the developing regions of the world (Africa, Central and South America, Asia, and the Pacific), asthma prevalence has been rising sharply with increasing urbanization and westernization.[6] The reasons for this increased prevalence remain largely unknown, but it has been noted to be associated with a parallel rise in atopic sensitization and increase in other allergic conditions (e.g. eczema and rhinitis). While there is unquestionably a genetic component to asthma, it is possible that changing patterns of environmental influences, such as exposure to microorganisms, pollutants, indoor and outdoor allergens, exert a strong influence on the development of the disease in susceptible individuals.

Allergens and occupational factors are considered to be the most important triggers of asthma. For successful long-term management of asthma, these triggers must be identified and the prevention of exposures should be the first line of defense.[7,8] National and International guidelines for the diagnosis and management of asthma recommend controlling allergen and irritant triggers contributing to asthma severity.[2,3]

Several epidemiological studies have shown a correlation between allergen exposure and the risk of developing asthma.[9-11] For example, there is a dose response relationship between levels of house-dust mite allergen found in the beds of infants of atopic parents at the age of two to three months and asthma at school age.[12] Symptoms and need for medication correlate with the level of household exposure of known allergens in susceptible individuals.[11,13] Improvement in asthma symptoms occurs when allergen exposure is reduced.[14-17]

The important allergens for children and adults appear to be those that are inhaled. Important indoor allergens include a number of domestic factors: House dust mites; cockroach allergen; fungi (Alternaria, Aspergillus, Cladosporium and Candida); and warm-blooded animals (cats, dogs and rodents). Rodents are problematic as they excrete urine, feces, saliva and dander that can be highly allergenic. Removal of a pet from the home of a sensitized patient is encouraged, but it may require several months before allergen levels decrease.[18] These antigens have also been identified in locations where there are no pets residing, including homes, schools, day care centers and work environments. Controlled trials of animal dander avoidance have been reported to be successful in schools and homes without an animal.[19] House dust has been shown to be composed of several organic and inorganic compounds, including insects and insect feces, mold spores, mammalian danders, pollen grains, fibers, mites and mite feces. In poor and inner city locations, mouse and rat allergen exposure and sensitization are common in children who have asthma.[20] Rodent exposure is also common in underdeveloped regions of the world and must be considered in asthma control in these populations.

Single-intervention efforts to improve environmental allergen control in the home are not likely to improve asthma control. For example, a study using allergen-impermeable mattress covers failed to show significant differences between intervention and control populations.[21] Single-interventions are likely to be unhelpful because most of the patients are sensitized to more than one allergen. Multiple-intervention environmental control studies have been conducted in high-risk urban asthmatic children with comprehensive allergen reduction methods. They have demonstrated positive outcomes.[16,22,23] Studies that have shown effective interventions include construction remediation, aimed at moisture sources within the homes of those with documented mold problem,[23] and home visits by community health workers who promote dust mite and cockroach control. Home visits have stressed behavior changes, such as smoking cessation, and offer an individualized approach to address pressing concerns, including asthma-related questions and social issues (e.g. housing, income). Multiple visits are required to encourage the completion of asthma action plans and deliver resources to reduce exposures. These have included allergy control pillow and mattress encasements, low-emission vacuums, commercial-quality doormats, cleaning kits, roach bait and rodent traps. Such multiple intervention programs have advocated for improved housing conditions and provided much needed education and social support. Overall, targeted home-based environmental interventions can improve health and reduce health care costs for poorly controlled asthmatics that live in resource poor communities.[24] A list of effective measures of environmental control is listed in Table 68.3.

TABLE 68.3: Avoiding asthma triggers: Effective environmental control

- Stop smoking and avoid exposure to second-hand smoke.
- Use insecticides to eliminate cockroaches from the house (if the patient can stay away for some time).
- Shake mattresses, pillows, bedspreads and blankets and expose them to the sun as often as possible.
- Remove carpets from the bedroom; minimize number of stuffed toys for children and wash them weekly.
- Avoid piling up books, toys, clothes, shoes and other items that accumulate dust in the bedroom.
- When cleaning the house: Sprinkle the floor with water before sweeping to avoid raising dust; clean furniture with a damp cloth.
- Wash the sheets and blankets on the patient's bed weekly in hot water.

  A temperature of >130°F is necessary for killing house-dust mites (but will not remove the allergen). Cold water and detergent/bleach wash is also acceptable.
- If available, encase pillow and mattress with allergen-impermeable cover.
- If possible, avoid exposure to gas stoves and appliances that are not vented to the outside, fumes from wood-burning appliances or fireplaces, sprays or strong odors.

Outdoor allergens include pollens (mainly from trees, weeds and grasses), fungi, molds and yeasts, but these agents carry less risk for asthma.[25] Grass and ragweed pollens have been especially associated with seasonal asthma symptoms.[26,27] Food allergens while an important cause of anaphylaxis, are not common precipitants of asthma symptoms.

Both outdoor and indoor pollutants contribute to worsening asthma symptoms.[28-32] They may directly trigger bronchoconstriction and act indirectly to worsen asthma by increasing bronchial hyperresponsiveness. This would further enhance responses to inhaled aeroallergens, as well as other provoking agents. The two main outdoor pollutants are industrial smog (sulfur dioxide particulate complex) and photochemical smog (ozone and nitrogen oxides). Whether long-term exposure is injurious or not, presently remains unclear. It is advisable to recommend to asthmatic patients to avoid, to the extent possible, exertion or exercise outside, when levels of air pollution are high.

Indoor pollutants include cooking and heating fuel exhausts, as well as insulating products, paints and varnishes. Modern construction techniques have been suspected of causing greater indoor air pollution. In energy-efficient buildings, there is 50% less turnover of fresh air. Formaldehyde and volatile organic compounds, such as isocyanates have been implicated as potential risk factors for the onset of asthma and wheezing.[30-32] Clinicians should advise patients to be aware of the potential irritating effects of newly installed furnishings and finishes, which can arise from new linoleum flooring, synthetic carpeting, particleboard, wall coverings, furniture and fresh paint.

The use of poorly vented gas stoves and appliances results in increased indoor levels of NO_2 and has been associated with increased respiratory symptoms.[33,34] Installing non-polluting, more effective heating in the homes of children with asthma does not significantly improve lung function, but can reduce symptoms of asthma, days off school, health care utilization, and visits to a pharmacist.[35] Also, fumes from wood-burning appliances or fireplaces, commonly used for heating and cooking in poor, underserved regions of the world, can precipitate symptoms in persons who have asthma.[36] Sprays and strong odors, particularly perfumes, can also irritate the lungs and precipitate asthma symptoms.

In asthmatics, active smoking is a cause of worsening symptoms and the deterioration of lung function and also reduces the efficacy of inhaled and systemic corticosteroids in treating asthma.[37,38] Long-term passive cigarette smoke exposure has been linked to new-onset asthma in children and adults, as well as worsening asthma symptoms, decreased lung function, and greater use of health services in those with preexisting asthma.[39] Children are more likely to be affected when the mother smokes rather than others in the household.[40] Tobacco smoke exposure in adults with asthma may be more likely to occur in the work environment.[41]

Estimates of the prevalence of occupational asthma vary.[42,43] It has been reported that 2 to 15% of all cases of adult-onset asthma arise from workplace exposure. Taking an occupational history can be very rewarding and can lead to primary prevention and avoidance of the offending environment. Patients should be questioned about exposure to animals, shellfish, fish and arthropods. They may cause asthma in farmers, grain handlers, and laboratory and poultry workers. Exposure to wood, plants and vegetables can cause asthma in woodworkers, carpenters, grain handlers, bakers and tobacco workers. Exposure to enzymes and pharmaceuticals should be questioned in pharmaceutical workers, pharmacists and detergent industry workers. Solderers, spray painters, electronics workers, and chemical and polyurethane manufacturers are another susceptible group. And, electroplaters, hard metalworkers, polishers, and solderers may have asthma caused by metals and metal salts such as aluminium, chromium, cobalt, nickel and platinum fumes.

Monitoring Asthma: Use Objective Measures of Asthma

Pulmonary Function Tests

Objective measurements of pulmonary function are important in patients with asthma to confirm the diagnosis and to assess disease activity from time to time. While there is a poor correlation between the airway inflammation and lung function,[44,45] measurements of the physiological consequences of asthma are extremely important in the control and management of asthma. Physiological testing can demonstrate the major diagnostic features of asthma: (1) airflow obstruction, (2) reversibility of airflow obstruction, and (3) bronchial hyper-responsiveness, and therefore can be useful in confirming the diagnosis. The following four tests of pulmonary function are extremely useful for establishing the diagnosis of asthma and/or for following the clinical course of the patient once the diagnosis has been made: (1) Spirometry; (2) Peak Expiratory Flow (PEF) measurements; (3) Pulse oximetry and/or arterial blood gas analysis; and (4) Bronchoprovocation testing.

Physiologic tests are also important tools to assess the disease activity of asthma. The perception of asthma symptoms by the patient is often poor, especially in the elderly or if the patient has had long-standing asthma.[46-49] Also, the physician's findings on physical examination may either overestimate or underestimate the severity of the airflow obstruction. Although the measurements of lung function do not correlate that well with patient-reported symptoms, they do add an objective measure to the assessment of how well the disease is controlled and have been proven to be important tools in the management and control of asthma.[50,51]

i. *Spirometry* is useful for the diagnosis of asthma and for following clinical outcomes.[52] Airflow obstruction, a classic feature of asthma, can be demonstrated on spirometry using the timed vital capacity maneuver. The test provides a quantitative assessment of asthma and can be used in children who are five years of age and older, The Forced Vital Capacity (FVC), which is the total amount of volume exhaled and the FEV_1, which is the volume exhaled in the first second of expiration are measured. The patient's results are compared with reference values based on age, height, sex and race.[53] A reduced FEV_1 and ratio of FEV_1/FVC show the presence of airflow obstruction.

A brisk improvement in spirometry (post-bronchodilator FEV_1 increases more than 12% and 200 mL), 10–20 minutes after the inhalation of a short-acting beta agonist can demonstrate the second cardinal feature of asthma reversibility.[53,54] Some patients with asthma never meet the reversibility criteria after repetitive testing with a short-acting bronchodilator. In such patients, after vigorous treatment, the FEV_1 may show significant improvement on a subsequent clinic visit and this would strongly support a diagnosis of asthma. A single post-bronchodilator test, therefore can not be used to exclude the diagnosis of asthma.

Regular monitoring of pulmonary function is important for asthma patients. It is helpful after treatment has been initiated to document improvement and also during the periods of worsening symptoms to offer an objective assessment of airflow obstruction. Spirometry has been advised atleast every one or two years to monitor lung function.[2] Physicians have a poor ability to assess the degree of airflow and patients too often can not perceive the severity of their disease.[50,51,55,56] One study reported that one-third of the children who had moderate-to-severe asthma based on symptoms, were reclassified to a more severe asthma category when pulmonary function was considered.[57] This is especially important in patients with poor lung function, as a low FEV_1 is associated with an increased risk of severe asthma exacerbations.[58,59] On the other hand, another study showed that a majority of children who had mild-to-moderate asthma classified by symptoms had normal FEV_1.[60] The assessment of reversibility to an inhaled short acting bronchodilator correlates with the degree of airway inflammation and can also offer an assessment of future risk.[61] A pronounced increase in FEV_1 after a bronchodilator is a strong marker of subsequent risk of death from asthma. In one study, compared with subjects with 15 to 24% reversibility in FEV_1, asthmatics with 25 to 49% and those with more than 50% reversibility had a 2.7 and 7.0 higher risk of death from asthma, respectively.[62] In addition, those patients who have the greatest degree of reversibility in response to a short-acting bronchodilator may be at the greatest risk of developing fixed airflow obstruction and have the greatest loss of future lung function.[63]

ii. *PEF: Short-term home monitoring* with the PEF meter can be useful in diagnosing asthma and identifying environmental triggers of asthma and can detect early signs of deterioration when symptoms change. Long-term monitoring is useful for those with severe brittle asthma and for those who have a poor perception of asthma symptoms. Spirometry, however, is the preferred method for measuring lung function to classify asthma severity as peak flow measures may underestimate airflow obstruction, particularly with more severe disease.[64,65] Peak flow measurements ideally should be done 10–20 minutes after inhaling a β-agonist. A zone system has been developed[3] for patient ease as follows: Green is 80 to 100% of the personal best peak flow measurement and shows good control; yellow is 50 to 80% of the personal best and signals caution that asthma is not under sufficient control; and red is less than 50% of personal best and signifies danger and the need for immediate physician intervention.

A diurnal variation in PEF of 20% is the diagnostic of asthma. The magnitude of peak flow variability is in general proportional to the severity of the disease. A high degree of variability signals unstable asthma that demands increased medication.

iii. *Oximetry/ blood gas analysis:* Virtually all asthmatic patients have hypoxemia during an acute exacerbation; the more severe the attack, the lower the arterial oxygen tension. Oximetry or arterial blood gas analysis is helpful during a severe attack and would not be generally done in the routine management of stable asthma.

iv. *Inhalation challenge testing* is useful in some patients when the diagnosis of asthma is not secure.[66] This occurs when the patient has normal peak flow rates and spirometry findings, yet typical asthma symptoms are present. Increasing concentrations of an agonist, such as methacholine are inhaled and if the FEV_1 drops 20% below baseline at any standard dose, the test result is positive, supporting the diagnosis of asthma. A negative test rules out asthma.

Measures of Inflammation

The presence and quantification of various inflammatory cells and mediators in sputum and body fluids have been used to reflect the activity of inflammation in asthma. These biomarkers of disease activity, such as sputum eosinophil counts, have mainly been used for clinical investigation. Elevated levels of Nitric Oxide (NO) have been detected in the exhaled air of asthmatic subjects. Exhaled NO is well established as a marker of eosinophilic inflammation. A standardized method of measurement must be carefully followed to prevent spurious results.[67] It has been shown to be a fairly effective screening tool with a sensitivity of 88% when there are levels of 20 parts per billion or greater in patients with asthma symptoms. Unfortunately, exhaled NO levels do not correlate with disease severity, but serial measurements may aid in monitoring disease activity. It has shown promise, for example, in identifying pending exacerbations of asthma. The availability of a low cost handheld analyzer may lead to future use in resource poor regions, although the scope for both false positives and false negatives remains significant.[68]

Treatment of Stable Asthma

Asthma Pharmacotherapy

i. *Beta 2-adrenoceptor agonists*: Selective inhaled β 2-adrenoceptor agonists are the main bronchodilating agents for the treatment of asthma, through their rapid and potent effects in relaxing airway smooth muscle. Their classification is according to the duration of action: Short and long acting. They produce bronchodilation by direct stimulation of the airway smooth muscle leading to relaxation via the activation of the adenylate cyclase pathway. Inhaled agents are preferred and they can be delivered by metered-dose inhaler, dry-powder capsules, and compressor-driven nebulizers. Corticosteroids upregulate the expression of β 2-adrenoreceptors by increasing the transcription of the gene.

   Short-Acting Beta-Agonists (SABAs), such as salbutamol, are widely used due to their acute (4–6 hour) bronchodilator effects and for the ability to protect against various challenges such as cold air, exercise and allergen. They are generally well tolerated, even with frequent use. They should be used as guide for symptom control. Anti-inflammatory treatment should be given when the use of SABAs become excessive (> 2x/week).

   Long-acting Beta-agonists (LABAs), mainly salmeterol and formoterol, provide bronchodilation and improve bronchial responsiveness for up to 12 hours. Like SABAs they also inhibit the acute early allergic response, but in addition, they inhibit the late phase response and airway hyperresponsiveness lasting up to 34 hours after allergen challenge.[69] The use of LABAs as monotherapy should be avoided in the stable asthmatic. Conclusions from a large randomized study[70] showed that LABA monotherapy may increase asthma-related deaths and hospitalizations, especially in certain ethnic groups. A large meta-analysis showed that the concomitant use of inhaled steroids appears to modify this effect.[71] Side effects are generally uncommon with inhaled LABA therapy (Table 68.4).

ii. *Inhaled corticosteroids (ICS):* Since their introduction in the early 1970s, ICS have become the mainstay of treatment in persistent asthma. This is because of its proven efficacy, above any other class of asthma therapy and also its lower potential for systemic side effects compared to oral glucocorticosteroids. It exerts its anti-inflammatory activity via the glucocorticoid receptor complex that regulates the gene transcription of proteins that inhibit proinflammatory cytokines. ICS have highly lipophilic compounds that have much higher binding affinity compared to hydrocortisone and also a highly efficient first-pass hepatic metabolism, resulting in lower systemic absorption. Clinically, they improve airway inflammation, hyperresponsiveness, airflow obstruction and symptoms in asthmatics. In the stable persistent asthmatic with persistent symptoms, adherence to ICS treatment is of paramount importance as it has been associated with the decreased risk of near fatal and fatal asthma (Fig. 68.2).[72]

   Establishing the dose-response relationship characteristics of ICS have been challenging as there is a relatively flat dose-response relationship and characteristics do vary between patients. The impetus for discovering the lowest effective dose in any patient is to minimize the potential systemic side effects especially when used over many years. In adults with mild to moderate asthma, most of the therapeutic benefit of budesonide is achieved at 200–400 mcg/day and its maximum effect at 1,000 mcg/day.[73] Equipotent daily therapeutic doses of beclomethasone are estimated to be between 200 and 500 mcg; doses higher that 1,000 mcg are discouraged because of the risk of absorption leading to systemic side effects. Dose response curves of fluticasone have been seen to plateau at lower doses (100–200 mcg).[74] Side effects of ICS are both local and systemic (Table 68.4). They are generally well tolerated, especially at lower doses.

iii. *Theophylline*: The xanthines, particularly theophylline, are the most widely prescribed oral therapy for the maintenance of stable asthma worldwide. In the 1980s, the introduction of the slow release preparation that provided more steady plasma levels was a large cause of its widespread use. The weak bronchodilator effect of theophylline on the airways can be

TABLE 68.4: Pharmacological agents for stable asthma

Pharmacological agent	*Potential adverse effects*	*Therapeutic considerations*
Corticosteroids (Glucocorticoids)	Cough, dysphonia, oral candidiasis	The use of chamber devices and mouth washing after inhalation decreases local side effects
Inhaled: Beclomethasone dipropionate, Budesonide, Flunisolide, Fluticasone propionate, Triamcinolone acetonide	In high doses, systemic effects may occur. Although studies are not conclusive, and clinical significance of these effects has not been established since it has been studied for long periods (e.g. adrenal suppression, osteoporosis, growth suppression, and skin thinning and easy bruising)	The risk-benefit ratio of uncontrolled asthma to the limited risks of inhaled corticosteroids should be considered.
Systemic: Methylprednisolone, Prednisolone, Prednisone	Short-term use: reversible hyperglycemia, increased appetite, fluid retention, psychological alterations, hypertension, gastric ulcer, and rarely aseptic necrosis of femur. Long-term use: adrenal axis suppression, growth retardation, dermal thinning, hypertension, diabetes, Cushing's syndrome, cataracts, muscle weakness	Use at lowest effective dose. For long-term use, alternate-day am dosing may produce less adverse effects.
Cromolyn Sodium and Nedocromil	15 to 20% of patients complain of an altered or unpleasant taste from nedocromil.	Therapeutic response to cromolyn and nedocromil often requires a 4 to 6 week trial to determine response clinically. Safety is the main advantage of these agents.
Long-Acting Beta2-Agonists	Tachycardia, muscle tremor, hypokalemia, prolongation of QT interval in overdose.	Not for monotherapy or clinical asthma exacerbations.
Inhaled: Salmeterol Formoterol	Tolerance may occur within 1 week of chronic therapy	Clinical significance of potentially developing tachphylaxis is uncertain
Oral: Albuterol, sustained-release		Inhaled long-acting beta2-agonists are preferred because they have fewer adverse reactions than oral agents.
Methylxanthines Theophylline, sustained-release tablets and capsules	Dose-related acute toxicities: tachycardia, nausea and vomiting, arrhythmias, headache, seizures, hematemesis, hyperglycemia, and hypokalemia.	Routine serum concentration monitoring is essential due to significant toxicities, narrow therapeutic range, individual differences in metabolic clearance and drug-drug interactions as well
Leukotriene Modifiers Zafirlukast, Montelukast Pranlukast	Well tolerated overall. One reported case of reversible hepatitis and hyperbilirubinemia; high concentrations may develop in patients with underlying hepatic disease	Administration with meals decreases bioavailability
Zafirlukast	Limited case reports of reversible hepatitis	Zafirlukast can inhibit the metabolism of terfenadine, warfarin, and theophylline.

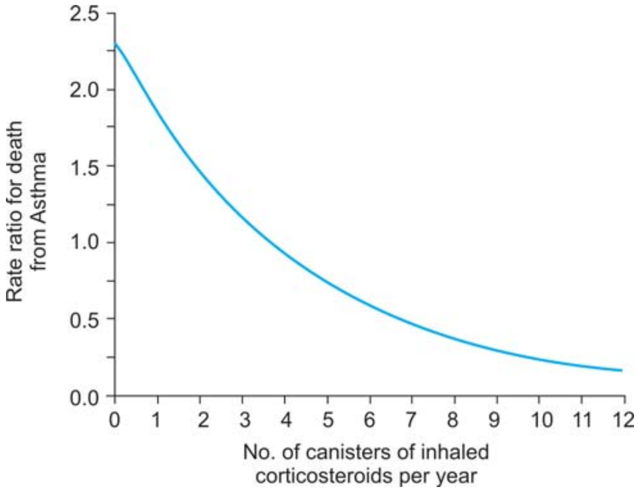

Fig. 68.2: Relation between death due to asthma and use of corticosteroids per year. Suissa S et al. Fitted Rate Ratio for Death from Asthma as a Function of the Number of Canisters of Inhaled Corticosteroids Used during the Year before the Index Date. NEJM. 2000; 343:332-6.

demonstrated *in vitro* on human airway tissues and it may result from inhibition of phosphodiesterases especially type III and IV.[75] Inhibition of these phosphodiesterases also appears to have anti-inflammatory effects and also inhibits the late response to allergen challenge.[76] The guidelines recommend that theophylline may be considered for use as add-on therapy in patients, not well-controlled on low-dose ICS, but recommend LABAs as more effective with fewer adverse events.[77] For the patient with uncontrolled asthma, low-dose inhaled budenoside with theophylline compared to high-dose inhaled budesonide produced similar benefits[78] and this may be achieved at theophylline concentrations below the recommended therapeutic range of 5–15 mg/dl.

Despite its attractiveness, side effects and their frequency is the main limitation to its use (Table 68.4). This is especially pronounced in the elderly where polypharmacy and potential drug-to-drug interaction are becoming more frequent. Theophylline has a rather narrow therapeutic window and unwanted effects are usually seen at plasma levels above 20 mg/dl. To avoid untoward effects it is advisable to monitor blood theophylline levels.

iv. *Leukotriene pathway modifiers:* Substantial evidence exists for involvement of the cysteinyl leukotrienes in the pathophysiology of asthma. They exert a number of important pharmacological actions that contribute to airflow obstruction in asthma: Airway smooth-muscle contraction, edema formation and mucus secretion. Numerous studies have shown that leukotriene modifiers have protective effects against bronchoprovocative challenges and they ease bronchial obstruction in asthma patients.

The antileukotrienes may be used as first line therapy when anti-inflammatory therapy is needed, but they are generally less effective than ICS. They also have less effect compared to LABA as add on therapy to ICS.[79] They may however have special role in the aspirin-sensitive asthmatic.[80] If one is chosen, a therapeutic trial of 4–6 weeks should be allowed to determine its effectiveness. There is currently no evidence that supports its use beyond this time if there is no symptomatic improvement. The leukotriene modifiers may have an additive effect to ICS and inhaled β-2 agonist in the severe asthmatic when step-up care is needed.[81,82]

Anti-leukotrienes are generally well-tolerated. In a safety study, over 3,000 patients, 4.5% developed reversible elevations of transaminases with zileuton after a few months of therapy.[83] Reports of Churg-Strauss syndrome after the initiation of Zafirlukast and Montelukast have also emerged, but it is likely that this has occurred as a result of systemic steroid withdrawal.

v. *Oral corticosteroids:* Systemic administration of corticosteroids are generally reserved for patients with severe asthma, or as trial of therapy to attempt to optimize lung function in patients with a component of fixed airflow obstruction despite conventional asthma therapies. Corticosteroids, such as prednisolone and methylprednisolone are rapidly absorbed across the gastrointestinal tract and have very high bioavailability. High doses (0.5–1.0 mg/kg/day) are recommended by most consensus documents for the treatment of severe exacerbations of asthma and should be avoided in the routine treatment of chronic stable asthma even at lower doses.

A summary of the therapeutic agents used for chronic stable asthma is listed in Table 68.4.

Biologic Therapies

Immunoglobulin E (IgE) is recognized as a key component of atopic asthma pathophysiology. Omalizumab is an IgE monoclonal antibody, which binds free IgE and decreases circulating IgE. It therefore, decreases allergen-driven cell degranulation and reduces the release of preformed proinflammatory mediators and newly synthesized cytokines.[84] This agent is used in difficult to control asthmatics who are not responding to conventional therapy. Interleukin (IL)-5 plays an important role in regulating the production, differentiation, recruitment, activation and survival of eosinophils. Neutralizing IL-5 with an antibody was regarded as a promising therapeutic strategy, however it does not appear to add significant clinical benefit in patients with asthma.[85]

Allergen Immunotherapy

Allergen-specific immunotherapy is the practice of administering gradual quantities of an allergen extract to a patient to ameliorate symptoms from subsequent exposures. Clinical evidence suggests that inhaled immunotherapy is effective to treat seasonal or perennial allergic rhinitis and asthma. It has also been shown to reduce the development of asthma in children with seasonal rhinoconjunctivitis.[86] Subcutaneous administration has generally been used and it is highly effective when the optimal does of high quality vaccine is administered. An important limitation of this route is the risk of potential side effects, which include systemic allergic reactions, occasional anaphylaxis and, even, fatalities.[87] As a result, safer approaches, such as sublingual immunotherapy, have been used to induce tolerance to inhaled antigens.[88] Allergen immunotherapy should always be combined with appropriate allergen avoidance strategies. The mechanisms of immunotherapy are based on a restored balance between Th2 and Th0/Th1 cells, inducing a reduction of inflammation in the target organ. Clinical indications and relative contraindications offered by the WHO, 1998 position paper[89]are shown in Table 68.5.

TABLE 68.5: Allergen Immunotherapy*

Allergen immunotherapy is indicated in the following circumstances:
- IgE-mediated disease (symptoms on exposure to relevant allergen supported by a positive SPT/RAST to that allergen)
- Inability to avoid allergen
- Inadequacy of drug treatment
- Limited spectrum of allergies
- Patients who understand risks and limitations of treatment.

Relative Contraindications:
- Coexistent uncontrolled asthma (within the UK, presence of asthma is considered a relative contraindication).
- Patients taking beta blockers
- Patients with other medical/immunological disease
- Small children (less than five years)
- Pregnancy (maintenance injections may be continued during pregnancy)
- Patients unable to comply with the immunotherapy protocol.

* Bousquet J, Lockey RF, Malling HJ. WHO Position Paper. Allergen immunotherapy: therapeutic vaccines for allergic diseases. Allergy. 1998; 53 (Suppl 44):1-42.

Antifungal Therapy

Airborne exposure to fungi is a common phenomenon worldwide. Fungal sensitization is uncommon, but in some asthmatics it can greatly affect the course of their disease.[90] There are three main recognized syndromes related to fungal sensitization and asthma: Allergic Bronchopulmonary Aspergillosis (ABPA), Allergic Bronchopulmonary Mycosis (ABPM) and trichophyton asthma. While anti-fungal therapy can not eliminate the exposure to fungal elements, it can be effective in these syndromes. Itraconazole is effective adjunct therapy in the treatment of stable ABPA together with oral corticosteroids and in asthmatics with SAFS it can improve quality of life measures and lung function.[91,92]

Diet and Asthma

Epidemiological data has long supported the notion that differences in diet may lead to different predisposition to allergic disorders. This association to the course and the control of the asthmatic patient, however is a much different concept. The International Study of Asthma and Allergies in Childhood (ISAAC), asthma prevalence was lowest in those countries with the highest dietary fat intake and those with a Mediterranean diet.[93] Numerous studies have since examined the relationship between dietary nutrients, fruits and vegetables for possible associations with asthma. While nutrients, such as vitamins A,C, E, various fatty acids, and increase in fresh food and vegetables appear promising, evidence from prospective and randomized trials are lacking.[94] Maternal nutrition on the fetus during pregnancy may have a role in subsequent childhood asthma, but data on this subject remains scarce. Intervention studies promoting the avoidance of cow's milk and eggs during pregnancy have failed to protect the infants from asthma.[95] General advice for patients with stable asthma, however needs to be based on the individual and their atopic history as there are no consensus recommendations currently. Eating a balanced diet in natural foods and vegetables seem to be intuitive and would probably yield benefits in other disease areas.

Patient Education

Asthma management plans have become popular, especially with high-risk patients. They are designed to give patients the skills for routine management, their disease and how to recognize and control the exacerbations of symptoms (Table 68.6). Evidence is now abundant that asthma self-management education is effective in improving outcomes of chronic asthma.[96-100] Benefits from self-management education include reduction in symptoms, less limitation of activity, improvement in the quality of life and perceived control of asthma, and improved medication adherence.[101-107] Also, death from asthma can be reduced. The use of a peak flowmeter, a written action plan and oral glucocorticoids prior to a severe attack can impact mortality.

A written action plan should include instructions for daily management, including what medications to use and how to avoid specific triggers relevant to the patient, and for recognizing and handling worsening asthma. Patients should know how to recognize the signs and symptoms of worsening asthma and how peak-flow measurements can be used to recognize an attack. It should also include what medications to take in response to these signs, what symptoms and peak-flow measurements indicate the need for urgent medical attention and the logistics of obtaining the required urgent medical care. Written action plans are particularly recommended for patients who have moderate or severe persistent asthma, who have difficulty perceiving the signs of worsening asthma and for those with a history of severe exacerbations or poorly controlled asthma.

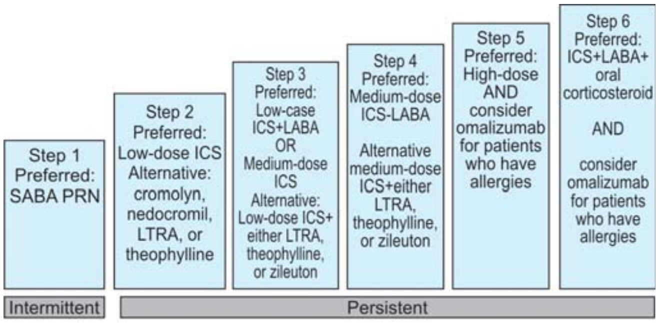
TABLE 68.6: Essential elements of asthma self-banagement program

- **Develop active partnership with patient and family**
  - – Provide an open two-way communication
  - – Establish realistic goals of successful therapy
  - – Discuss treatment preferences
  - – Explore barriers to successful treatment.
- **Offer basic knowledge of asthma causes and how to avoid triggers**
  - – Identify potential environmental allergens
  - – Discuss occupational triggers
  - – Avoid outside exposure on high pollution days.
- **Give pharmacy-based education**
  - – Difference between controller and rescue medications
  - – Role of each medication prescribed
    - proper inhaler technique
    - MDI (with holding chamber or spacer)
    - dry powder inhalers.
- **Provide patient with action plan for**
  - – Daily control
  - – Recognition and management of acute exacerbations of symptoms
  - – Where and when to seek help.
- **Explain how to measure asthma control**
  - – Peak flowmeter use
  - – Home diary or asthma control tests.
- **Offer when available computer and Internet programs for asthma care**

TREATMENT PROTOCOLS FOR ASTHMA

Asthma is an episodic disease and the clinical presentation and natural history is highly variable from patient to patient and for any individual patient. Some patients have persistent symptoms and exacerbations from time to time. Others show long periods of remission, with sudden worsening with exposure to asthma triggers (Fig. 68.1). Treatment protocols are based on this variability and use a step-care pharmacological approach based on the intensity of the asthma over time[2,3] (Fig. 68.3). As symptoms and lung function worsen, step-up or add-on therapy is given. As symptoms improve, therapy can be "stepped down."

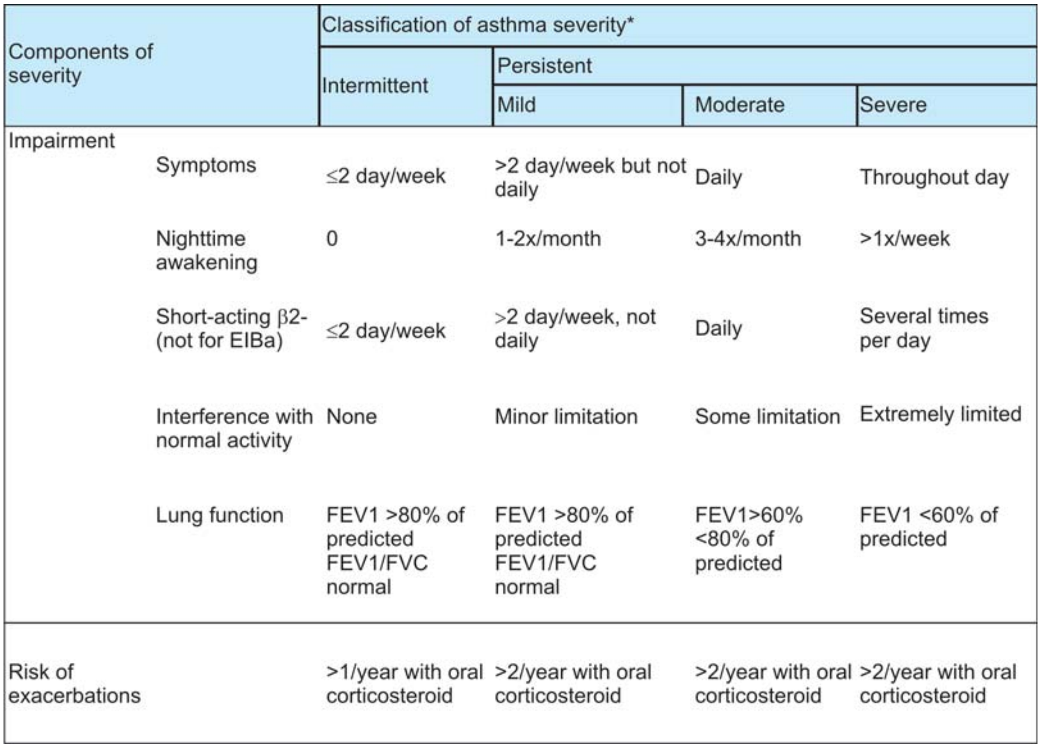
It has been challenging to clinicians to quantify the degree of asthma for any given patient and to make decisions based on that assessment regarding treatment. Lung function was often used as the primary endpoint, but because of the poor correlation between lung function and patient symptoms and outcomes, a composite of measures has been suggested by international asthma guidelines. Initially, they were based on a scale of disease severity.[2,3] Asthma severity can be considered the intrinsic intensity of the disease. It is advocated for use when a patient is not receiving long-term control therapy. The components of current impairment include daily symptoms, night-time awakenings, need of quick relief



Step 1
Preferred:
SABA PRN
Step 2
Preferred:
Low-dose ICS
Alternative:
cromolyn,
nedocromil,
LTRA, or
theophylline
Step 3
Preferred:
Low-case
ICS+LABA
OR
Medium-dose
ICS
Alternative:
Low-dose ICS+
either LTRA,
theophylline,
or zileuton
Step 4
Preferred:
Medium-dose
ICS-LABA
Alternative
medium-dose
ICS+either
LTRA,
theophylline,
or zileuton
Step 5
Preferred:
High-dose
AND
consider
omalizumab
for patients
who have
allergies
Step 6
Preferred:
ICS+LABA+
oral
corticosteroid
AND
consider
omalizumab
for patients
who have
allergies
Intermittent
Persistent

SABA = short-acting beta$_2$-agonist; ICS = inhaled corticosteroid; LTRA = leukotriene receptor antagonist; LABA = long-acting beta$_2$-agonist.

Fig. 68.3: Guidelines for the diagnosis and management of asthma



Components of severity		Classification of asthma severity*			
		Intermittent	Persistent		
			Mild	Moderate	Severe
Impairment	Symptoms	≤2 day/week	>2 day/week but not daily	Daily	Throughout day
	Nighttime awakening	0	1-2x/month	3-4x/month	>1x/week
	Short-acting β2- (not for EIBa)	≤2 day/week	>2 day/week, not daily	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	FEV1 >80% of predicted FEV1/FVC normal	FEV1 >80% of predicted FEV1/FVC normal	FEV1>60% <80% of predicted	FEV1 <60% of predicted
Risk of exacerbations		>1/year with oral corticosteroid	>2/year with oral corticosteroid	>2/year with oral corticosteroid	>2/year with oral corticosteroid

rescue therapy, work/school days missed, interference with normal daily activities and lung function, measured by spirometry (Fig. 68.4).

When symptoms are more than two times per week, nocturnal symptoms are more than twice per month or FEV_1 is less than 80% of predicted, regular treatment with anti-inflammatory therapy (low-dose inhaled corticosteroids preferred) is recommended and the patient is considered to have "persistent" asthma. The response to therapy, that is how the manifestations of asthma have been reduced or removed, is the degree of asthma control achieved. Asthma control has two components: The level of clinical asthma control (symptoms and quality of life) and the risk of future adverse events (exacerbations of asthma, loss of lung function, side effects of the therapy). At each visit, the patient should be assessed for the level of asthma control, adherence to the recommended treatment and for potential side effects of the drugs used. A simplified scheme to identify patients who are controlled, partly controlled and poorly controlled has been developed (Table 68.7).[2,3] Several composite control questionnaires have been developed to help the clinician assess asthma control.[108-112] Step-up therapy is advised for patients not well controlled according to guideline recommendations. There are no hard and fast rules on stepping down asthma care, but atleast three months of stability is recommended until a reduction in medication is tried. The lowest dose of medication to maintain stability is offered. At each step, reliever medication with a SABA is used for breakthrough symptoms, but increased use implies poor control and need for step-up therapy.

Significant reductions in the rate of severe exacerbations and improvements in the quality of life can be achieved by aiming at achieving guideline-defined asthma control and by adjusting therapy to achieve it. At the end of one year, with the use of an inhaled corticosteroid and LABA, 30% of the patients can achieve total control (i.e. the absence of any sign or symptom of asthma), and 60% had achieved well-controlled asthma.[113] For those who do not reach adequate control, step-up care is given according to the guidelines. Helpful general guidelines for the use of asthma medications are given in Table 68.8.

TABLE 68.7: Classification of Asthma Control youths >12 years and adults*

Characteristics of impairment	*Controlled (All of the Following)*	*Not well controlled (Any measure present in any week)*	*Very poorly controlled*
Daytime symptoms	None (d ≤ 2/week)	> 2 times/week	Throughout day
Interference with normal activities	None	Any	Extremely limited
Nocturnal symptoms/awakening	< 2 times/month	1-3 times/week	> 4 times/week
Need for short-acting beta agonist (rescue treatment)	None(d ≤ 2/week)	> 2 times/week	Several times a day
Lung function (PEFR or FEV_1)	> 80% predicted or personal best	60-80% predicted or personal best	< 60 predicted or personal best
Validated Questionnaire (e.g. ACT score)	> 20	16-19	15 or less

TABLE 68.8: Principles of Asthma Treatment

1. Use rescue medication (SABA) for symptoms of dyspnea, wheezing and chest tightness at any stage
2. Begin anti-inflammatory medication (inhaled ICS preferred) when symptoms occur two or more times a week
3. Do not use LABA bronchodilators continuously as solo treatment
4. Adding LABA to ICS is preferred approach when step-up therapy is needed
5. Medium or high dose ICS may be necessary to control persistent symptoms, but risk more systemic absorption
6. Sustained-released theophylline is a bronchodilator with weak anti-inflammatory properties and frequent side effects
7. The use of a spacer device is recommended when MDI cannisters are used to reduce oropharyngeal deposition and reduce systemic absorption; consider the use of single or multi-dose Dry Powder Inhalers (DPIs). They are easier to use correctly that MDIs
8. Systemic corticosteroids have many side effects. They may be necessary for severe asthma; oral use is preferred over intramuscular or intravenous delivery

SABA: short-acting beta agonist; **LABA:** long-acting beta agonist; **ICS:** inhaled corticosteroid; **MDI:** metered dose inhaler

ASTHMA CONTROL IN DEVELOPING COUNTRIES

More than 500 million patients live in developing countries or in deprived populations. They have received insufficient attention from the health care community, government officials, media, patients and families.[114] While the value of asthma disease management interventions has been well documented, they are expensive and difficult to implement, especially in developing countries where the infrastructure for the diagnosis and management of chronic diseases, such as asthma, is either not available or is viewed as low priority on the public-health agenda. In addition, surveillance systems and diagnostic services are often poorly developed, and the true burden of diseases, such as asthma and occupational lung disease is largely unknown. It is evident that asthma is mostly under-diagnosed and under-treated (particularly in children), causing a high morbidity and a significant mortality.

The World Health Organization (WHO) has given priority to the prevention and control of chronic diseases, such as asthma, with special emphasis on developing countries.[115] Models have been developed like the WHO-Practical Approach to Lung Health (PAL).[116] This is an initiative for low and middle-income countries that is focused on improving the management of patients with respiratory symptoms in the primary care setting and, improving the efficiency of the delivery of respiratory services within a district health care system, with a focus on coordination and integration of respiratory case management. The program uses standardized clinical practice guidelines that have been developed to suit the local needs. Key components are: (1) providing guidance, technical support and assistance with funding; (2) assuring access to essential diagnostics and drugs; and (3) education for health care workers in these activities.

Using a PAL educational outreach program for the integrated case management of chronic respiratory diseases has been used in poor, underdeveloped regions such as in South Africa.[117,118] Combining educational outreach delivered to nurse practitioners by health department trainers, and integrated case management has provided a promising model for disease prevention and improved care for respiratory diseases such as asthma. With local adaptations of international asthma guidelines, success with asthma control in resource poor areas have been also reported from Latin America.[119,120] Important suggestions for asthma control of patients in low and middle-income countries are suggested by the World Health Organization in the "Practical Approach to Lung Disease Handbook."[121]

In the majority of developing countries, diagnostic tests like spirometry that are required for the diagnosis and assessment of severity of asthma are not readily available, resulting in incorrect assessment and under-diagnosis of asthma. Most asthmatics who live in developing countries and in deprived areas often have limited access to essential drugs as they are either not available or not affordable.[122] The Asthma Drug Facility has been proposed by the International Union to address this issue and make good quality essential asthma drugs available to all patients who live in low- and middle-income countries.[123] Steps have been taken by the Union to ensure a transparent, straightforward and efficient approach.

Similarly in India, the Government of India and WHO (India) had developed asthma-management guidelines for use at the primary levels of health care. The guidelines advocate a simple algorithmic approach based on the local conditions and feasibility.[124]

CONCLUSION

The approach to the patient with asthma has undergone a great transition in recent years. Successful outcomes can be expected for most patients. International guidelines have underscored the importance of controlling the underlying inflammation that drives the manifestations of the disease. A step-up approach has been advocated, beginning with a short-acting beta agonist for infrequent symptoms. For persistent symptoms, inhaled corticosteroids are recommended as first-line therapy. Monitoring with objective measures of disease activity, including pulmonary function and symptom questionnaires, have been advised and patient education programs can lead to self-reliance, better adherence to therapy and improved outcomes. The challenges in asthma control faced by underdeveloped countries can be overcome with educational outreach programs adapted to local needs and resources.

Management of Severe Asthma

Liesel D'Silva, Parameswaran Nair

INTRODUCTION

There is no universally accepted definition of difficult or chronic severe asthma. Using the consensus definition of American Thoracic Society (ATS), severe asthma has been defined as persistent symptoms, airflow limitation and treatment resistance.[1] A patient who requires prolonged treatment with oral corticosteroids for $\geq$ 50% of the year and/or high dose inhaled corticosteroids along with two or more minor criteria (use of daily long-acting bronchodilators, daily or near daily use of rescue medication, persistent airflow obstruction, one or more emergency visits per year, three or more courses of oral corticosteroids per year, rapid clinical deterioration if the corticosteroid dose is reduced by $\leq$ 25% or history of near fatal asthma) is diagnosed with severe asthma.

As the phenotype of severe asthma is less common (up to 10%) than other forms of asthma and there are no validated animal models of severe asthma, multicenter networks have been initiated to characterize severe asthma phenotypes.

The "European Network for Understanding Mechanisms of Severe Asthma" (ENFUMOSA)[2] is the first, large, multicenter European program designed to understand the mechanisms involved in chronic severe asthma. This, along with US based networks such as the Severe Asthma Research Program (SARP) (chartered by the US National Heart, Lung, and Blood Institute)[3] and The Epidemiology and Natural History of Asthma: Outcomes and Treatment Regimens (TENOR)[4] have suggested that severe asthma might be a distinct disease or a different form of asthma rather than only an increase in asthma symptoms.

Severe asthma includes the phenotypes controlled by, and those resistant to, currently available high-intensity therapy. More importantly, proper treatment of severe asthma can shift the disease to be controllable (Fig. 69.1).[5]

Although, difficult asthma may account for only 5 to 10% of adult asthma,[6,7] chronic severe asthma contributes to 40 to 50% of health care costs[8] owing to unscheduled doctors' visits, frequent hospital admissions and drug consumption.

DEVELOPMENT OF SEVERE ASTHMA

Development of severe asthma is rather complicated. In addition to macrophages, mast cell, eosinophil and Th2 lymphocyte-associated inflammation, neutrophilic

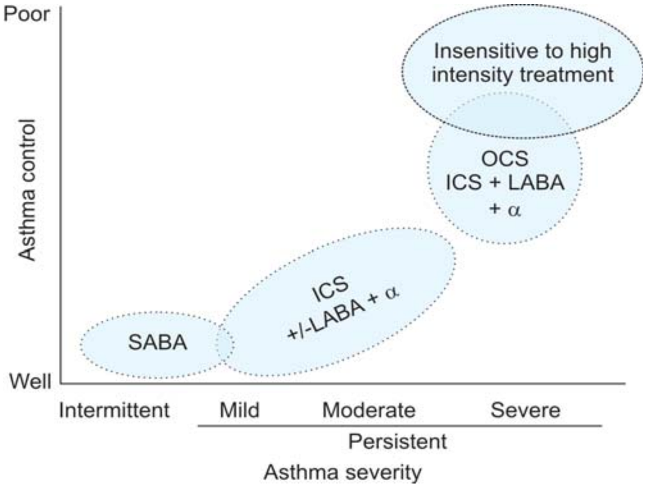

Fig. 69.1: Asthma severity and asthma control. The x-axis shows asthma severity and y-axis shows the level of asthma control. Severe asthma includes high-intensity treatment dependent patients and high-intensity treatment resistant patients

α: others; ICS: Inhaled corticosteroids; LABA: Long acting β2 agonists; OCS: Oral corticosteroids; SABA: Short-acting β2 agonists inflammation and airway remodeling are seen in severe refractory asthma. Risk factors such as genetics, and environmental conditions, such as infection, pollution, smoking, diet and global warming, might contribute to the development of severe refractory asthma.[5]

PHENOTYPES IN SEVERE ASTHMA

Chronic severe asthma is a heterogeneous condition that has different clinical, etiological, physiological and pathophysiological features making phenotyping an important aspect of this disease. Phenotyping of severe asthma is important because it will improve our understanding of the underlying mechanisms, natural history, prognosis and current and future therapeutic interventions for this subset of patients. *In vitro* studies showed that theophylline improved corticosteroid sensitivity only in the HDAC-defect group[9] and formoterol/salmeterol improved corticosteroid sensitivity only in the severe asthma with defective Glucocorticoid Receptor (GR) nuclear translocation.[5,10] Therefore, in future, identification of molecular or pathological abnormality will be most important for identifying an effective treatment. This approach will help to individualize appropriate therapy and avoid the overuse of corticosteroids in patients who have corticosteroid resistant disease and will help to develop novel phenotype-specific therapies.

Clinical Phenotypes

A cluster analysis in difficult asthma patients identified four clusters.[11] The first cluster described a subgroup of early onset of atopic asthma, with the evidence of airway dysfunction, symptoms and eosinophilic airway inflammation. This cohort was associated with significantly greater number of previous hospital visits and asthma exacerbations requiring oral corticosteroids and had a higher rate of failed clinic appointments compared with the other refractory clusters. The second cluster included obese patients with a female preponderance, evidence of asthma symptoms, and an absence of eosinophilic airway inflammation. The third cluster was a subgroup with refractory eosinophilic disease, with recurrent exacerbations, but relatively few symptoms. The other severe-specific cluster was a subgroup with early onset of atopic disease with virtually no eosinophilic inflammation but with symptoms. Molecular typing using gene arrays has the potential to detect asthma phenotypes.[12]

In clinical practice, severe asthma phenotypes are characterized by a variable combination of:

- Frequent severe asthma exacerbations
- Irreversible airway obstruction
- Systemic steroid dependent asthma.

Frequent Severe Asthma Exacerbations

The cause of frequent exacerbations in severe asthma could be related to the underlying susceptibility to respond abnormally to viral respiratory infections, allergens, occupational agents, environmental pollutants and discontinuation of corticosteroid therapy. Increased airway responsiveness,[13] air trapping and early airway closure[14] and blunted perception of dyspnea[15] are some of the factors responsible for the abnormal response. Risk factors that favor the exacerbation prone phenotype include psychological disorders and nasal polyposis,[16] low baseline FEV_1, early age at onset, allergic status, aspirin sensitivity[17] and airway eosinophilic inflammation.[18]

Irreversible Airway Obstruction

Some severe asthma patients display irreversible airflow limitation associated with significant health problems and a rapid decline in lung function and are therefore likely to have a poorer prognosis.[19] It is difficult to distinguish the airway obstruction in these patients from the smoking related chronic airflow limitation seen in patients with Chronic Obstructive Pulmonary Disease (COPD). However, several of these patients do retain some degree of bronchodilator reversibility to β2-agonists.[19] The reasons why these patients suffer from an accelerated decline in lung function are unclear. This feature has been associated with late onset of the disease, severe airway hyperresponsiveness to methacholine,[20] intense granulocytic inflammation of the airways particularly refractory eosinophilic and neutrophilic inflammation,[21,22] and chronic or recurrent infection with pathogens, such as *Chlamydia pneumoniae* that can lead to ongoing inflammation and subsequent structural changes in the airway wall.[23]

Systemic Steroid-Dependent Asthma

Many patients with severe asthma show a reduced response to inhaled and oral corticosteroids and require high doses of prednisone (>30 mg) to control their asthma symptoms but deteriorate as soon as the dose of corticosteroid is tapered. The relatively corticosteroid-insensitive asthmatic patient, also labeled the Corticosteroid-Dependent (CSD) patient, is part of a spectrum of patients that ends with the extreme Corticosteroid-Resistant (CSR) asthma.

There are different molecular mechanisms to explain corticosteroid resistance in asthma.[24] Corticosteroids act through a cytosolic GR that is activated by ligand binding and translocates to the nucleus. Once in the nucleus it can bind to DNA and in combination with coactivator proteins, switch on the expression of anti-inflammatory genes such as MKP-1. Alternatively, activated GR can recruit corepressor proteins that can suppress the activity of proinflammatory transcription factors such as NF-κB and AP-1. These activation steps may be attenuated in severe asthma because of oxidative stress or cigarette smoking, viral infection, allergen challenge or chronic inflammation. High levels of IL-2 and IL-4 can repress GR ligand binding, Mitogen-Activated Protein Kinases (MAPKs) activation can reduce GR nuclear translocation and Phosphoinositide 3-Kinase (PI3K) activation can reduce GR corepressor activity.

Genetics could also have role in corticosteroid resistance in asthma. Reduction in Histone Deacetylase (HDAC) activity, particularly HDAC2, has been observed in severe asthma, leading to some degree of steroid nonresponsiveness.[25] Mutation of the Corticotropin-Releasing Hormone Receptor-1 (CRHR-1) is also associated with corticosteroid resistance.[26] Unlike familial corticosteroid resistance where there are mutations in GR, CSR patients have normal cortisol levels and are not Addisonian.[27]

Obesity and Asthma

There is an increasing body of evidence suggesting that obese asthma is a new phenotype of asthma[28] because it may be characterized by greater severity,[29] increased utilization of health care resources, decreased asthma control[30] and impaired response to glucocorticosteroids.[31,32]

Cross-sectional and prospective studies show variable association between asthma and obesity, ranging from no effect up to an odds of three or more.[28,33] Most of the studies have examined Body Mass Index (BMI), but it is still not clear whether other measures, such as body fat distribution would add more value than BMI.[28] There is conflicting data on whether there is an association between obesity and airflow obstruction or AHR in asthma.[34,35] It is plausible that obesity associated systemic inflammation can enhance airway inflammation in asthma. Animal studies show that high serum leptin (adipokine) enhances airway inflammation,[36,37] whereas high serum adiponectin (anti-inflammatory adipokine) concentration attenuates allergen-induced airway inflammation;[38] however more recent data suggest that there is no involvement of systemic adipokines between obesity and asthma.[39,40,41] Contrary to studies that have reported obese asthmatics to have eosinophilic inflammation less commonly,[42] there was no association between BMI and airway inflammation in a cross-sectional study.[43] The mechanism for the obesity-asthma association is unknown. The proposed theory that oxidative stress due to obesity may cause airway inflammation and lead to asthma is not supported by a study that showed a lack of association between plasma F2-isoprostane levels and asthma and obesity.[44] There is growing evidence to suggest a genetic basis for obesity and asthma.[45,46]

Although, epidemiologic and animal evidence demonstrate a strong link between obesity and asthma, there are no clinical studies in obese asthma clearly demonstrating the effect of obesity on airflow obstruction, AHR and airway inflammation. Therefore, it is still debatable whether obese asthma is a unique phenotype of asthma. Further prospective studies in which both obesity and asthma are well characterized are needed to better understand the underlying mechanisms. Randomized controlled trials are needed to determine the best therapeutic options for obese asthma.

The Key Aspects of Severe Asthma Phenotypes

Differences in Severe Asthma between Children and Adults

It is more difficult to study severe asthma in children than in adults, there is a greater variability in the outcomes. Atopic features, such as eczema and allergic rhinitis may be common features of severe asthma in children.[47] Severe asthma in children is more likely in males, whereas severe asthma in adulthood is more common in women.[48]

Duration of Asthma

Adult asthmatic patients whose asthma onset was in adulthood had a similar decline in lung function as those with childhood onset, despite the shorter overall duration of disease. Late onset asthma is associated with less atopy by skin test, lower IgE levels and fewer symptoms with allergen exposures.[47,48] These data suggest that the development of severe asthma may not require an atopic predisposition. Adult-onset asthma is a significant risk factor for chronic airway obstruction (odds ratio 3.3).[20]

Persistent Abnormalities of Lung Function

There is a large subset of patients with severe asthma who manifest chronic airflow obstruction. However, the specific cut-off point for postbronchodilator FEV_1 was less than 75% predicted in one study[20] and less than 50% predicted in another study.[49] Patients with chronic airflow limitation were older and had longer duration of disease. They also had elevated residual lung volumes because of chronic air trapping but normal diffusion capacity (not suggestive of emphysema). Bronchial wall thickening is seen on high resolution computed tomography scans in chronic airway obstruction.[49]

Fraction of Exhaled Nitric Oxide

The data on Fraction of Exhaled Nitric Oxide (FeNO) are variable and inconsistent from study to study.[3,49,50,51,52] There is no consensus on the discriminant value or interpretation of FeNO in severe asthma as compared with other asthma phenotypes.

Eosinophils in Airway

Eosinophil is an important biomarker of some key features of severe asthma. The presence of chronic airway obstruction has been linked to both increased eosinophils in sputum (≥ 2%, OR= 8.9)[20] and in blood (OR= 6.3).[31] Severe asthma can be characterized as eosinophil positive and eosinophil negative according to the presence or absence of eosinophils in the endobronchial biopsies.[29] The presence of eosinophils in the endobronchial biopsies from severe asthma patients despite chronic high-dose oral corticosteroid treatment indicate corticosteroid resistance. Fewer eosinophils in biopsies are seen in patients with early onset severe asthma than in typical early onset asthma. Eosinophil negative biopsies have predominance of neutrophils.

Mechanistic Observations in Severe Asthma

Interleukin-13 (IL-13) is a Th2 cytokine associated with allergic inflammation. Over expression of IL-13 is observed in sputum and bronchial biopsy specimens in severe asthma patients as compared with mild asthma and control groups.[53]

Lipoxins (lipoxygenase interaction products) are potent anti-inflammatory lipid mediators, which may attenuate allergic inflammation. Lipoxin blocks the Granulocyte Macrophage-Colony Stimulating Factor (GM-CSF), which is a potent eosinophil survival factor. Defective lipoxin and lipoxin receptor generation may lead to enhanced eosinophil survival, persistent inflammation and poor response to steroids, and is a unique characteristic of severe asthma.[54,55]

Chitinase, a broad-spectrum protease, has been identified in airway samples from asthmatic patients and is quantitatively correlated with the degree of airway remodeling and asthma severity. Mammalian chitinase activates Protease-Activated Receptor Type-2 (PAR-2) in human airway epithelial cells, which lead to a variety of inflammatory processes.[56] YKL-40, a chitinase like protein, was elevated in patients with asthma and correlated with severity of disease, pulmonary function and thickness of the subepithelial basement membrane.[57] Moreover, elevated YKL-40 expression is under genetic control and CH13L1, the chitinase 3-like 1, gene that encodes YKL-40 has been identified.[58]

Mechanisms of Corticosteroid Insensitivity

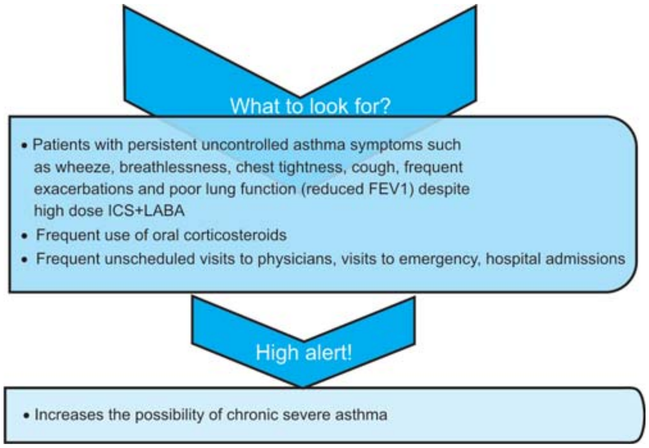
The reduction in corticosteroid responsiveness has been ascribed to the following factors:[5]

- Reduced number of glucocorticosteroid receptors (GR).
- Altered affinity of the ligand for GR.
- Reduced ability of the GR to bind to DNA because of phosphorylation.
- Increased expression of inflammatory transcription factors, such as AP-1, that competes for DNA binding.
- Deficiency of HDAC2 which is an important cofactor for GR function.
- Cigarette smoking is an oxidative stress that can affect GR nuclear translocation and expression of HDAC2.
- Neutrophilic inflammation.
- Respiratory viruses (adenovirus, rhinovirus) are implicated in corticosteroid resistance. The exact mechanism is not clear but oxidative stress, prevention of GR nuclear translocation and reduction in HDAC2 activity could be some of the reasons for corticosteroid insensitivity subsequent to viral infection.
- Airway remodeling.
- Overexpression of interferon regulatory factor (IRF) transcription factors activated by interferon.

Diagnosis

Diagnosis of chronic severe asthma is suspected from the presence of several important clues[59] (Fig. 69.2).

It is important to confirm whether the patient really has asthma or a disease that mimics asthma. The latter includes COPD, bronchiectasis, constrictive bronchiolitis, congestive heart failure, upper airway obstruction, dysfunctional breathing, vocal cord dysfunction, Allergic Bronchopulmonary Aspergillosis (ABPA), hypersensitivity pneumonitis, Churg-Strauss syndrome and eosinophilc pneumonia. Coexisting conditions such as tuberculosis, frequent respiratory infections including *C. pneumoniae* and *M. pneumoniae*, severe nasal and sinus



- Patients with persistent uncontrolled asthma symptoms such as wheeze, breathlessness, chest tightness, cough, frequent exacerbations and poor lung function (reduced FEV1) despite high dose ICS+LABA
- Frequent use of oral corticosteroids
- Frequent unscheduled visits to physicians, visits to emergency, hospital admissions

- Increases the possibility of chronic severe asthma

Fig. 69.2: Diagnostic algorithm for chronic severe asthma

disease, gastroesophageal reflux, psychological factors (anxiety, depression, panic and fear), obstructive sleep apnea and obesity can worsen asthma control. It is always good to look for unusual triggers such as occupational sensitizers, household irritants (e.g. mosquito repellants), food additives, smoking, drugs (aspirin, NSAID, ACE inhibitors), thyrotoxicosis and menstruation that can aggravate asthma.

Investigations

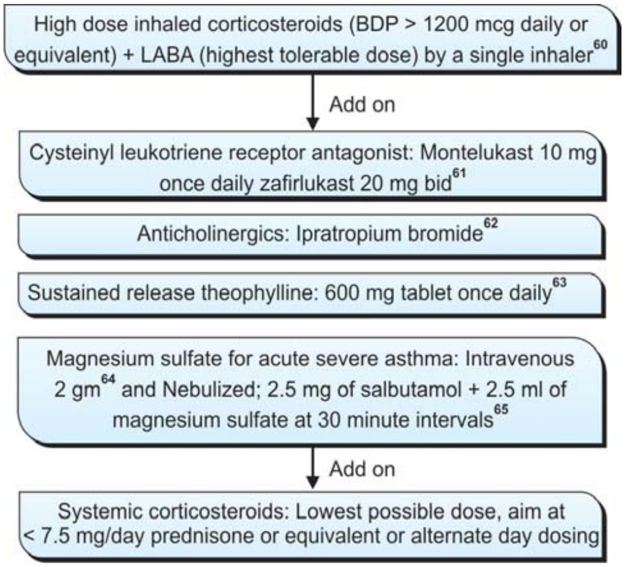
Various methods are given below by which investigation can be done:[7]

- Thorough medical history particularly for poor compliance with medication and under treatment
- Check inhaler technique
    - Blood Tests
    - Blood eosinophil count
    - Total serum IgE, allergen skin prick test
    - Bood theophylline levels or serum cortisol (to support adherence)
    - Other blood tests depending on clinical features (α1-antitrypsin, angiotensin-converting enzyme, immunoglobulins, antineutrophilic cytoplasmic antibody, aspergillus serology)
- *Pulmonary Function*
    - Spirometry: Bronchodilator reversibility, flow volume loop, lung volumes, transfer factor
    - Bronchial challenge test
- *Noninvasive Markers of Airway Inflammation*
    - Quantitative sputum cell counts
    - Exhaled nitric oxide
- *Radiography*
    - Chest X-ray
    - High resolution computed tomography of the lungs (to look for bronchiectasis, interstitial lung disease)
    - Computed tomography of nasal sinuses (to look for nasal disease)
- *Other Tests (As Clinically Indicated)*
    - Nasal endoscopy (to exclude polyps, rhinosinusitis)
    - Bronchoscopy (to look for tumors, foreign body)
    - Laryngoscopy during symptomatic episodes (to examine for vocal cord dysfunction)
    - Echocardiogram (to differentiate "wheeze" that may be due to cardiac causes)
    - Psychiatric assessment
    - Cardiopulmonary exercise testing (to evaluate whether exercise intolerance and exercise related symptoms have a pulmonary or a nonpulmonary origin)

Management

Treatment of chronic severe asthma should aim to achieve the best possible asthma control and quality of life with the least possible medication. The choice of therapy depends upon the severity of disease and includes:[41]

- Conventional pharmacotherapy (Fig. 69.3)
- Immunomodulating pharmacotherapy
- Biological therapy



High dose inhaled corticosteroids (BDP > 1200 mcg daily or equivalent) + LABA (highest tolerable dose) by a single inhaler[60]

Cysteinyl leukotriene receptor antagonist: Montelukast 10 mg once daily zafirlukast 20 mg bid[61]

Anticholinergics: Ipratropium bromide[62]

Sustained release theophylline: 600 mg tablet once daily[63]

Magnesium sulfate for acute severe asthma: Intravenous 2 gm[64] and Nebulized; 2.5 mg of salbutamol + 2.5 ml of magnesium sulfate at 30 minute intervals[65]

Systemic corticosteroids: Lowest possible dose, aim at < 7.5 mg/day prednisone or equivalent or alternate day dosing

Fig. 69.3: Conventional pharmacotherapy

Monitor Side Effects

LABA: Tachycardia, palpitations, tremors

ICS: Hoarseness, oral thrush, reflex cough

Systemic corticosteroids: Osteoporosis, diabetes, hypertension, cataract formation, gastrointestinal upsets (dysphagia, abdominal pain, gastrointestinal bleeding), Cushingoid features.

Laboratory Monitoring

Bone mineral density, fasting blood sugar, blood pressure.

Concomitant Therapy

Calcium, vitamin D and/or bisphosphonates, proton pump inhibitors.

Immunomodulating Pharmacotherapy

In order to minimize the chronic need for systemic corticosteroids and reduce their adverse effects, an exploratory trial for 24 to 36 weeks with alternative anti-inflammatory and immunomodulatory therapies, such as methotrexate, oral gold, cyclosporine, Intravenous γ-globulin (IVIG), macrolide antibacterials and azathioprine, should be considered. Regular monitoring of patients' symptoms and laboratory parameters are mandatory to avoid side effects.

Methotrexate: Methotrexate is a folate antagonist that retains its anti-inflammatory activity at a low dose of 5 to 25 mg/week. However, the mechanism of action remains unclear. Eleven clinical trials and three meta-analyses have evaluated oral or intramuscular methotrexate in the dose of 7.5 to 30 mg/week for 12 to 28 months.[41] In a recent study,[66] a substantial reduction (>50%) in the steroid dose was observed in the methotrexate group. Common side effects include liver function abnormalities, abdominal pain, diarrhea, nausea, oral ulcers and stomatitis, but they are usually transient and reversible and seldom life threatening.

Gold: Gold is an immunomodulatory agent whose mechanism of anti-inflammatory action is unknown. Three prospective studies have examined the efficacy of gold[67,68,69] administered for a duration of six to eight months. In the largest trial, the Auranofin Multicenter Drug Trial, 3 mg twice daily for eight months significantly reduced the daily oral corticosteroid dose by ≥ 50% in corticosteroid dependent asthma.[69] Gold is well tolerated and side effects, such as abdominal pain, diarrhea and pruritic rash are common, but self limited.

Cyclosporine: Cyclosporine is a fungal metabolite that has immunomodulatory and anti-inflammatory effects. To date, three small prospective randomized trials have examined the effect of cyclosporine (loading dose 5 mg/kg/day) in patients with steroid-dependent asthma for short periods of 3 to 11 months.[70,71,72] Serious side effects of dose-dependent nephrotoxicity were not observed at low doses in these trials, but several patients experienced hypertrichosis, worsening of preexisting hypertension, paresthesias, tremor, headache and flu like symptoms.

Intravenous Immunoglobulin (IVIG): There is very limited experience with IVIG therapy in asthma.[73] Two prospective trials have examined the effects of IVIG therapy (2 g/kg loading dose followed by 400 mg/kg infusion every three weeks for three months) in severe steroid dependent asthma, of which one trial was stopped prematurely. There was no significant reduction in the corticosteroid dose, but the post-hoc analysis did show a median reduction from 16.4 mg to 3 mg/day in patients needing high dose corticosteroid therapy.[74] Minor side effects include headache and nausea and are self limiting. Avoid IVIG therapy in patients with IgA deficiency. In addition to uncertainties on clinical efficacy, its high cost and limited availability in the global market are likely to prevent its widespread use.

Macrolide Antibacterials: Macrolide antibiotics particularly troleandomycin (14 mg/kg/day, maximum dose of 1 gm/day) for 12 to 24 months[75] and clarithromycin 500 mg twice daily for 12 months[76] have decreased corticosteroid requirements in steroid-dependent asthma that has correlated with a subjective improvement of symptoms. The improvement does not appear to be related to the direct antibacterial effect, but has been attributed to the inhibition of corticosteroid metabolism by the hepatic cytochrome P450 complex. Steroid related side effects are common with troleandomycin. Bacterial resistance has not been reported. Empirical treatment with macrolides especially clarithromycin may be considered in patients with severe corticosteroid dependent asthma as it has a better safety profile than troleandomycin.

Thiopurines: Azathioprine has a corticosteroid sparing effect in steroid refractory ulcerative colitis[77] and steroid-responsive vasculitis[78] in a dose of 2 to 2.5 mg/kg/day. However, there is very limited evidence to support the use of azathioprine as a steroid sparing agent in steroid dependent asthma and large, well designed, long-term studies are required before any recommendation in clinical practice can be made.[79]

Biologic Therapy

Asthma is a syndrome of airway inflammatory diseases. The immunological pathogenesis of this airway inflammation is becoming increasingly important and provides an opportunity for targeted biological intervention for patients who fail to respond to alternative anti-inflammatory and immunomodulatory therapies. Targeted therapies include strategies to activate dendritic cells through the TLR-9 receptors, to interrupt the action of TH2 cytokines with cytokine blockers and monoclonal antibodies, to promote development of TH1 responses, to block IgE mediated pathways and to block TNF-α.

Dendritic Cell-Based Therapies

The dendritic cell presents the antigen to pattern recognition receptors such as Toll-Like Receptors (TLRs).[80] A large number of animal studies have demonstrated that activation of TLR-9 can result in the skewing of immune response towards TH1.[81] Preliminary studies with TLR-9 agonists in allergic rhinitis have not been very convincing, but additional studies are underway in allergic asthma.[82,83]

TNF-α Inhibitors

TNF-α is important in innate immune response. It is a cytokine, principally produced by macrophages in response to the activation of toll-like receptors, but is also produced by other proinflammatory cells including monocytes, dendritic cells, B lymphocytes, T lymphocytes, neutrophils, mast cells and eosinophils, as well as structural cells including fibroblasts, epithelial cells and smooth muscle cells. TNF-α levels are higher in those with severe asthma. TNF-α promotes eosinophilic and neutrophilic inflammation, contributes to airway hyperresponsivenss and airway remodeling in asthma. Corticosteroids fail to reduce TNF-α in asthmatic airways and therefore TNF-α contributes to glucocorticosteroid resistance. Based on these observations, blocking TNF-α could represent an advance in the management of asthma patients who are resistant to corticosteroids.[84,85] Biologic agents targeting TNF-α include infliximab (a chimeric mouse/humanized monoclonal antibody), etanercept (a soluble fusion protein combining TNF-α receptors with an FC fragment of human IgG1) and adalimumab (a fully human monoclonal antibody).[86]

Preliminary clinical studies showed significant improvement in patients with severe asthma refractory to glucocorticosteroid treatment, but some studies reported negative findings. In two small studies in chronic severe asthma, etanercept (25 mg twice/week subcutaneous infusion for 2 to 3 months) improved bronchial hyperresponsiveness, FEV_1 and quality of life, but surprisingly did not affect airway inflammation.[87,88] Infliximab was not effective in mild to moderate asthma.[89]

TNF-α inhibitors are well tolerated with common side effects such as injection site rash, headache, nausea and abdominal pain. Serious and rare side-effects are infections, particularly tuberculosis, solid organ malignancies, multiple sclerosis and worsening of cardiac failure.[90] Small molecule inhibitors of TNF-α Converting Enzyme (TACE) have also been developed.[91] Large multicenter clinical trials with etanercept and other anti-TNF-α monoclonal antibodies are in progress.

Anti-IgE Monoclonal Antibodies

Omalizumab, an IgE-specific humanized IgG1 monoclonal antibody binds to the Fc-region of the IgE molecule, prevents IgE from interacting with high or low-affinity IgE receptors (FcεR1 and FcεR11) and results in rapid decreases in levels of circulating free IgE.[92] Omalizumab has been successfully used to treat severe allergic asthma patients who continue to remain symptomatic despite optimum combination treatment.[93] Omalizumab is administered as a subcutaneous injection in a dose of 150 to 300 mg once every two to four weeks. In a pooled analysis of several large clinical trials, omalizumab significantly reduced asthma exacerbations (by 38%), emergency department visits (by 61%) and hospital admissions (by 52%) and unscheduled doctor visits (by 47%) when compared to control subjects.[94,95]

Omalizumab is the only biological therapy that is approved for asthma at this time. Common side-effects include injection site reaction, headache and pharyngitis. Peak therapeutic response is achieved 16 weeks after starting treatment[96] and therefore a clinical assessment needs to be made at 16 weeks after the initiation of therapy to determine the need to continue therapy. Omalizumab is approved for clinical use but is a limited option because majority of patients with chronic severe asthma are nonatopic. Additionally, the high cost of the drug is another limiting factor.

Lumiliximab (anti-CD23) is a human monoclonal antibody directed against the low affinity IgE receptor CD23 (FcεR11) which is expressed on several cell including monocytes, alveolar macrophages, B cells and dendritic cells of allergic individuals. CD23 is believed to have a role in the IgE-mediated inflammatory processes and its activation can result in the increased production of proinflammatory cytokines. A Phase I single dose trial in patients with allergic asthma resulted in decreased IgE levels by 40%, and *in vitro* studies showed reduced production of proinflammatory cytokines (IL-1β and TNF-α).[97] Additional studies are needed to determine the true clinical efficacy of this agent in asthma.

Th2 Cytokine-Blocking Therapies

The cytokines (IL-4, IL-5, IL-9 and IL-13) produced by TH2 type lymphocytes, basophils and mast cells promote allergic inflammation in asthma. Human studies have targeted IL-4, IL-5, IL-9, IL-13 individually and joint targeting of IL-4 and IL-13.[98]

Targeting IL-4: In the presence of dendritic cell-presented allergen, IL-4 strongly influences the differentiation of TH0 cells into TH2 cells. Along with IL-13, IL-4 promotes the switch from IgM to IgE by the B lymphocyte. IL-4 also upregulates IgE expression on mast cells and basophils and contributes to the recruitment of inflammatory cells and goblet cell hyperplasia in asthma.[99]

The solubilized IL-4 receptor fragment altrakincept inhibits binding of IL-4 to its receptor. Preliminary studies[100,101] with nebulized altrakincept maintained asthma control despite withdrawal of corticosteroids but a larger, Phase III trial[102] failed to confirm this benefit.

Pascolizumab, an anti-IL-4 humanized monoclonal antibody, did not yield impressive results in asthma patients and further development was discontinued.[84]

Targeting IL-5: IL-5 stimulates the development and release of eosinophils from the bone marrow, their enhanced adhesion to endothelial cells lining the postcapillary venules and their persistence, activation and secretion into the airways.[103] Most of the airway inflammation in asthma is because of the inappropriate accumulation of eosinophils which release proinflammatory mediators such as cytokines and chemokines. Given its central role in regulating the development and release of eosinophils, blocking IL-5 with Monoclonal Antibodies (mAb) was a potentially attractive target to blunt the eosinophilic bronchitis in asthma. In contrast to several clinical trials in which anti IL-5 mAb, “mepolizumab” was not successful in asthma of varying severity,[104-106] two small proof of concept studies[107,108] reported a decrease in asthma exacerbations in a subset of asthmatic patients who have a persistent blood and sputum eosinophilia despite treatment with systemic corticosteroids. This finding indicates that this particular phenotype of asthmatics might stand to benefit from use of an anti-IL-5 monoclonal antibody.

Targeting IL-9: IL-9 has a direct effect on the development and activation of human mast cells, contributes to goblet cell hyperplasia in the airways and to airway remodeling.[109] Phase I studies with anti-IL-9 monoclonal antibody (MEDI-528) have been completed in healthy subjects without major adverse events. Phase II studies are currently in progress in patients with symptomatic moderate to severe asthma.[98]

Targeting IL-13: As IL-13 and IL-4 share the same receptor, IL-13 has many functions similar to those of IL-4 but in addition IL-13 is important for epithelial cell maturation, goblet cell hyperplasia and mucous production, generation of extracellular matrix proteins and enhanced contractility of airway smooth muscle cells[110-112] IL-13 is also involved in the recruitment of eosinophils, monocytes, macrophages and T-cells. Human anti-IL-13 specific monoclonal antibodies are in Phase I and II trials. A Phase I clinical trial with CAT-354 showed that increasing single doses of intravenously administered anti-IL-13 monoclonal antibody in patients with mild asthma were well tolerated at all doses with no safety concerns, but we have yet to await data related to asthma outcomes.[113]

Joint Targeting of IL-4 and IL-13: IL-4 and IL-13 signal through the same surface receptor, IL-4R α which then activates the transcription factor STAT-6 which is required for many of their biologic functions.[114] Recombinant human IL-4 variant, “pitrakinra” given either as a subcutaneous dose or via nebulization twice daily for four weeks blocked the shared receptor IL-4R α to block the effects of both IL-4 and IL-13 and improved asthma outcomes.[115] Further large scale studies are required to establish the effectiveness and safety of this treatment.

Targeting Thymic Stromal Lymphopoietin (TSLP), IL-33 and other allergen-independent cytokine pathways which promote TH2 type allergic inflammatory disease to block chronic allergic inflammation are currently under investigation in animal models of asthma.[116]

T-Cell Blocking Therapies

Daclizumab (anti-IL-2 receptor α subunit/anti -Tac, anti-CD25) monoclonal antibody decreases T-cell proliferation and cytokine (TH1 and TH2) production. A proof of concept study with daclizumab, administered IV every two weeks in patients with moderate to severe persistent asthma improved pulmonary function and decreased blood eosinophils.[117]

Keliximab is an anti-CD4 monoclonal antibody that showed a dose-dependent decrease in peripheral CD4 counts but no significant changes in asthma symptoms in patients with steroid-dependent asthma.[118,119]

Promoting TH1 Cytokines

IL-12 and IFNγ downregulate TH2 response and drive the differentiation of TH0 cells towards a TH1 phenotype and therefore, may be a therapeutic option for treatment of allergic asthma. Injection of IL-12 in patients with mild asthma decreased blood and sputum eosinophils after allergen challenge but had no effect on the late phase asthmatic responses or in airway hyperresponsiveness. This therapy was associated with flu-like symptoms, abnormal liver function tests and cardiac arrhythmia.[120]

TH17 Cells as a Target

TH17 cells are a distinct type of T-helper cells which produce IL-17 cytokines that increase neutrophil infiltration.[121] IL-17 is also associated with steroid resistance in asthma.[122] Targeting this pathway may prove to be effective treatment of neutrophilic asthma.

IL-25 is another member of the IL-17 family that provokes TH2 response. Animal studies have shown that a neutralizing antibody against IL-25 significantly reduces airway hyperresponsiveness, reduces IL-5 and IL-13 production, reduces tissue eosinophil infiltration, goblet cell hyperplasia and serum IgE.[123] While human studies have not yet been reported, this might be a potential therapeutic target.

Other Potential Therapies

Since oxidative and nitrative stress may drive the corticosteroid insensitivity by attenuating the HDAC activity, antioxidants such as N-acetyl cysteine, fudostein or inhibitors of inducible NOS_2 should reverse corticosteroid resistance. As PI3K contributes to the defect in HDAC and JNK and p38, MAPK cause defective GR nuclear translocation, add-on treatment of these inhibitors might be useful to restore corticosteroid sensitivity. Two new products CRx-170, a combination of budesonide and low dose nortriptyline[124] and a new combination of prednisone and di-dypridamole[125] has been tested in asthma patients and showed promising results.

Novel Steroids: “Dissociated corticosteroids,” called nonsteroidal Selective Glucocorticoid Receptor Agonists (SEGRA) are now in clinical development.[126] These novel agents have the anti-inflammatory capacity of corticosteroids but with reduced side effects. However, these have not been tested in severe refractory asthma.

Another new steroid, in phase II trials, is TPI 1020.[127] This molecule is based on the corticosteroid budesonide but superior to budesonide in protecting against narrowing of the airways and it also inhibits migration of neutrophils into the lung (32.6% decrease vs 3.7% increase for budesonide) and their subsequent activation.

Eotaxin: Eotaxin is a chemokine that promotes recruitment of eosinophils by binding to the receptor CCR3 that is expressed on eosinophils. CCR3 is also expressed on basophils, mast cells, activated TH2 cells and airway epithelial cells.[128] Small molecule CCR3 antagonists such as N-ureidoalkyl-benzpiperidines,[129] YM-344031[130] and YM-355179[131] inhibited eoisnophil infiltration into airways in animal models. Furthermore, CCR3 antagonists also reduced airway hyperresponsiveness, goblet cell hyperplasia and airway remodeling in mice.[132] Therefore, CCR3 antagonists may be a promising therapy in asthma.

Cell Adhesion Molecules: Leukocyte extravasation, migration into interstitium, activation and tissue retention are regulated by cell adhesion molecules such as selectins (L-selectin, P-selectin, E-selectin, ICAM-1, and VCAM-1) and integrins (α1 and α2). The selectin antagonist, TBC1269 was shown to be effective in the animal models of allergic asthma.[114] The proof of concept study in patients with asthma suggests that inhaled TBC1269 may be more effective than the intravenous formulation in inhibiting the late phase asthma reactions.[133,134] Most of the small molecule integrin α4β1 antagonists were ineffective in preventing asthma symptoms. However a recent phase II trial with valategrast significantly improved lung function and reduced exacerbations in asthma patients who had their steroid treatment withdrawn, but further development of this molecule was discontinued because of safety issues.[135]

Statins: Statins exhibit anti-inflammatory properties by inhibiting the prenylation (not adhered to cell membrane) of signaling molecules such as Rho GTPases.[136] *In vitro* and mouse models suggest that statins inhibit the proinflammatory cell accumulation activation.[137,138] One study showed that simvastatin was not effective in mild to moderate asthma patients who respond to inhaled corticosteroids.[139] Since, the pleiotropic effects of individual statins differ, treatment with different statins may produce different results.[119,120] Their effectiveness in asthma needs to be confirmed with well designed randomized clinical trials.

Although *in vitro* and animal models have identified promising molecules targeted at the inflammatory component of asthma, the overall development of novel anti-inflammatory therapy for asthma has been disappointing in the clinical setting because of the lack of efficacy and safety issues. The way forward may be to reexamine the concept of combination therapy that would have a synergistic effect rather than monotherapy (e.g. CCR3 antagonist + anti-IL5mAb would inhibit eosinophil infiltration into the asthmatic lung).[120]

Bronchial Thermoplasty

The first non-pharmacological treatment for difficult-to-control asthma has recently been developed. Many of the symptoms in severe asthma patients are due to the excessive accumulation of smooth muscle bundles in the submucosa of these patients. Current treatments do not reduce the excess smooth muscle mass that is present in the remodeled airway in chronic asthma. Bronchial thermoplasty reduces the thickness of the hypertrophied bronchial smooth muscle in the airways and improves a patient's ability to breathe.[140] This novel approach is intended for patients $\geq$ 18 years, whose severe and persistent asthma is not well-controlled with inhaled corticosteroids and long-acting beta agonist medications.[141] The equipment used for the procedure called the 'Alair' system (Asthmatx, Mountain View, CA, USA), has been approved in April 2010 by the US Food and Drug Administration.[141] The Alair Bronchial Thermoplasty System[140] is composed of a catheter with an electrode tip that delivers a form of electromagnetic energy, called radiofrequency thermal energy, directly to the airways to ablate the hypertrophied bronchial smooth muscle. A controller unit generates and controls the energy. To obtain maximal benefit from the procedure, patients need multiple sessions targeting different areas in the lungs.

The initial trials of bronchial thermoplasty technique in dogs[142] and in mild asthma patients demonstrated clinical and functional improvement with only few adverse effects. Subsequently, randomized trials to assess the efficacy and safety of bronchial thermoplasty in asthma patients were initiated. The Asthma Intervention Research (AIR) Trial[143] and The Research in Severe Asthma (RISA) Trial[144] showed that at the end of 1 year of follow up, patients who had undergone bronchial thermoplasty showed a clinical and statistically significant improvement in FEV1, use of rescue medication, and asthma control scores in quality of life questionnaires. Although the patients treated with thermoplasty more often experienced adverse effects, such as dyspnea, cough, and wheezing, most of these were mild in nature and usually resolved in less than one week. As both, the AIR Trial and the RISA trial were not blinded, a third trial designated as Asthma Intervention Research 2 (AIR2) Trial,[145] included a placebo group in which asthma patients were sham-treated. The AIR2 Trial confirmed that in comparison with the sham-treated patients, symptomatic patients with severe asthma treated with bronchial thermoplasty had a significantly better quality of life with fewer severe exacerbations. A 3 years follow up of bronchial thermoplasty patients from multiple studies do not demonstrate clinical complications or deterioration of pulmonary function, indicating long-term safety with this treatment.[146] An analysis of chest CT findings performed five years after treatment in 15 patients also revealed no significant anatomical changes, confirming the absence of late anatomical deformities. Bronchial thermoplasty is still an experimental procedure, and we have to await regulatory approval for its clinical use.

MANAGING SEVERE ASTHMA USING AIRWAY INFLAMMATORY

The conventional strategies described above rely on symptoms and lung function to guide treatment particularly anti-inflammatory treatment. It is presumed that increased symptoms and worsening airflow obstruction are associated with a steroid-responsive bronchitis. However, clinical recognition by physicians of the presence and type of bronchitis is very poor.[147] Quantitative cell counts in sputum provide the most reliable and comprehensive and relatively non-invasive method to assess bronchitis. The clinical applications of this technique are well described elsewhere.[148,149] Briefly, sputum examination in a patient with severe asthma can identify three types of phenotypes that is helpful to plan investigations and treatment: Eosinophilic bronchitis, neutrophilic bronchitis and patients with normal sputum cell counts but with moderate to severe airway hyper-responsiveness (PC20 methacholine less than 2 mg/ml).

Patients with eosinophilic bronchitis are steroid sensitive. A reasonable treatment strategy would be to increase the dose of inhaled and ingested steroid to the optimum dose to control sputum eosinophilia (to less than 1%) by monitoring sputum counts at six weekly intervals. After the optimum dose of steroids are identified, novel prednisone-sparing strategies can be initiated. This includes investigations for causes of persistent eosinophilia (hypereosinophilic syndrome, vasculitis, chronic eosinophilic pneumonias, parasitic infestations, chronic rhinosinusitis, etc.) and evalution of drugs such as hydroxyurea, imatinib (in patients with PDGFR-FIPLI mutation) or mepolizumab. In highly atopic patients, omalizumab is another option although currently no adequately powered randomized controlled studies has conclusively shown a convincing steroid-sparing effect. Radical treatment of chronic rhinosinusitis is recommended as chronic hyperplastic rhinosinusitis is one of the most important predictors of persistent airway eosinophilia.[150] Fraction of exhaled nitric oxide is not helpful in monitoring response to corticosteroids in these severe patients.[151]

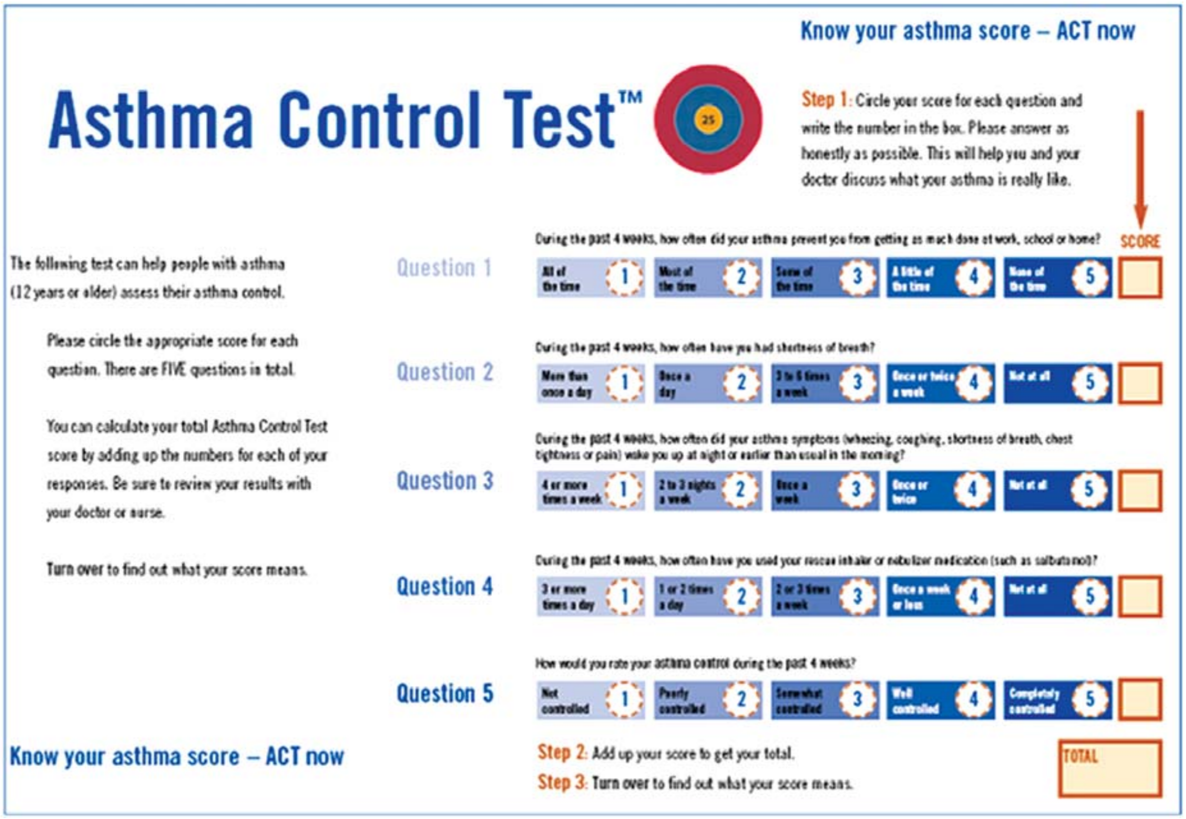
In patients with persistent neutrophilic bronchitis (total cell count greater than 25 million cells/g of sputum and neutrophils > 65%), high doses of corticosteroids are unncecessary. We would recommend reducing the dose of corticosteroids (by 5 mg decrease every 4-6 weeks) by carefully monitoring sputum cell counts to try and get patients off their corticosteroids or to the minimum dose to avoid adrenal suppression and concurrently investigate the cause of persistent neutrophilia.[152] These include detailed microbiology (including molecular diagnostic techniques for bacteria, viruses, fungi and *Chlamydia*), cystic fibrosis phenotype and genotype, innate immune deficiencies, neutrophil phagocytosis function defects, inflammatory bowel diseases, ciliary dysfunction, etc. Identification of specific causes help to institute specific therapies such as appropriate antimicrobial therapy, nebulized hypertonic saline, immunoglobulin replacement treatments, etc. Novel therapies directed against neutrophils and neutrophil activation products are currently being investigated for situations not associated with infective etiologies.

There is currently no specific therapies for patients with severe hyper-responsiveness not associated with a cellular bronchitis. Treatments directed against smooth muscle such as bronchial thermoplasty[145] is likely to be most beneficial for such patients. Other therapies that are likely to be beneficial in these patients are anti-TNF therapy, anti-leukotriene therapy and novel treatments that are currently being evaluated directed against IL-9 or IL-13.

MONITORING A PATIENT WITH DIFFICULT ASTHMA

It is unclear how best to monitor patients with difficult asthma. However, the following points should be considered:

- Regular follow-up
- Assess adherence to treatment, inhaler technique



Know your asthma score – ACT now

Asthma Control Test™

Step 1: Circle your score for each question and write the number in the box. Please answer as honestly as possible. This will help you and your doctor discuss what your asthma is really like.

The following test can help people with asthma (12 years or older) assess their asthma control.

Please circle the appropriate score for each question. There are FIVE questions in total.

You can calculate your total Asthma Control Test score by adding up the numbers for each of your responses. Be sure to review your results with your doctor or nurse.

Turn over to find out what your score means.

		1	2	3	4	5	SCORE
Question 1	During the past 4 weeks, how often did your asthma prevent you from getting as much done at work, school or home?	All of the time	Most of the time	Some of the time	A little of the time	None of the time	☐
Question 2	During the past 4 weeks, how often have you had shortness of breath?	More than once a day	Once a day	3 to 6 times a week	Once or twice a week	Not at all	☐
Question 3	During the past 4 weeks, how often did your asthma symptoms (wheezing, coughing, shortness of breath, chest tightness or pain) wake you up at night or earlier than usual in the morning?	4 or more times a week	2 to 3 nights a week	Once a week	Once or twice	Not at all	☐
Question 4	During the past 4 weeks, how often have you used your rescue inhaler or nebulizer medication (such as salbutamol)?	3 or more times a day	1 or 2 times a day	2 or 3 times a week	Once a week or less	Not at all	☐
Question 5	How would you rate your asthma control during the past 4 weeks?	Not controlled	Poorly controlled	Somewhat controlled	Well controlled	Completely controlled	☐

Step 2: Add up your score to get your total.

Step 3: Turn over to find out what your score means.

TOTAL ☐

Know your asthma score – ACT now

- Encourage weight reduction, smoking cessation
- Assess asthma control using a validated test such as the Asthma Control Test (ACT). An ACT score more than 20 indicates well-controlled asthma and a score less than 19 indicates uncontrolled asthma[153] (Fig. 69.4)
- Monitor disease activity using tests of airway hyper responsiveness and noninvasive markers of airway inflammation.

Referral to a Specialist

Patients who do not respond to guideline-based treatment should be referred to a specialist especially if the diagnosis is in doubt or when excessive amounts of drugs, especially oral corticosteroids, are used.

CONCLUSION

Management of severe asthma is challenging. Patients can be difficult to control despite use of current standard of care therapy, including inhaled corticosteroids and long-acting beta agonists. Alternative diagnoses, noncompliance, poor inhaler technique and comorbidities, all can influence asthma control and response to currently available therapy. Severe asthma has a distinct pathophysiology including airway remodeling that contributes to the decreased effectiveness of standard therapy. Severe asthma has multiple phenotypes that likely require distinct therapeutic approaches to achieve control and improve long-term health outcomes. New therapeutic approaches to these distinct phenotypes will improve our understanding and treatment of this difficult to manage disease.

Immunotherapy and Immunomodulators for Allergic Rhinitis and Asthma

Ruby Pawankar, Giovanni Passalacqua

INTRODUCTION

Allergies occur as a result of aberrant immune reactivity against common harmless environmental proteins called allergens. A key component of the pathomechanisms of allergic diseases is the production of Th_2 cytokines, generation of allergen-specific Immunoglobulin E (IgE), cross-linking of the IgE molecules by allergen, activation of mast cells with the release of potent mediators which, in turn, elicit the acute allergic reactions and initiate the development of chronic inflammation. Most therapeutic approaches for allergic diseases focus primarily on the symptom control and suppression of inflammation. Nevertheless, none of the available drugs are capable of modifying the immune response and their effects vanish within few hours or days after discontinuation. Specific Allergen Immunotherapy (SIT) is the only disease-modifying treatment for allergic rhinitis and asthma, which benefits may persist years after treatment is discontinued.

Allergen immunotherapy has been used for almost a century as a desensitizing therapy for allergic diseases. It was introduced in 1911 based on the empiric concept that administering the substances, which produce clinical manifestations in the allergic subject, would result in a sort of vaccination with consequent clinical benefit. Despite the rationale was wrong, the results were favorable. With a better knowledge of the mechanisms of the specific immunotherapy (Fig. 70.1), the development of improved allergen extracts and the studies done using these, there has been a marked improvement in our understanding of immunotherapy. Furthermore, the standardization of allergenic extracts allowed the availability of vaccines of high quality and safety. In fact, in 1998, the World Health Organization (WHO) published a position paper on SIT,[1] and further recommendations for the use of immunotherapy were reported in the ARIA.[2]

The standard modality of administration of SIT is the subcutaneous route (SCIT), but in recent years also the sublingual route (SLIT) achieved credibility and is now considered a viable alternative to Subcutaneous Immunotherapy (SCIT). Specific immunotherapy, both subcutaneous and sublingual, is currently indicated for respiratory allergy (rhinitis/asthma); whereas for hymenoptera venom allergy, only SCIT is used.

SUBCUTANEOUS IMMUNOTHERAPY (SCIT)

SCIT is an allergen-specific therapy that induces long-term remission of allergic rhinitis and allergic asthma and

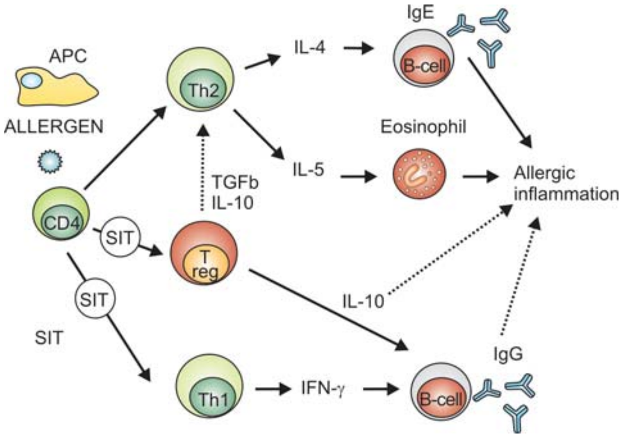

Fig. 70.1: Mechanisms of immunotherapy

in contrast to pharmacotherapy, i.e. symptomatic, SCIT prevents the onset of new sensitizations,[3,4] and reduces the progression of disease from allergic rhinitis to allergic asthma.[5] Such responses involve immunological memory and therefore direct and/or indirect effects on T and/or B lymphocytes.

Indications

- In ascertained IgE-mediated respiratory diseases (supported by a positive SPT/RAST) and when the causal role of the allergen(s) is well established.
- In patients with clinical symptoms due to a single or limited spectrum of allergies.
- In patients inadequately responding to drug treatment.
- In patients unwilling to use medication.
- In patients in whom pharmacotherapy induces undesirable side effects.

Contraindications

- Coexistent uncontrolled asthma/severe asthma
- Patients taking beta-blockers
- Patients with other medical/immunological diseases, including major cardiovascular disease, cancer or chronic infections
- Small children less than 5 years (relative contraindication)
- Pregnancy (maintenance injections may be continued during pregnancy, but it is recommended not to start induction phase in pregnancy)
- Patients unable to comply with the immunotherapy protocol or with psychiatric disorders

Efficacy

The clinical efficacy of SCIT is well established, both for rhinitis and asthma. A review of 43 Double-Blind Placebo-Controlled (DBPC) trials has confirmed an efficacy (improvement of symptoms greater than 30% as compared to placebo) in 75 to 80% of the studies.[6] This clinical efficacy is associated with a marked reduction in for the use of anti-allergic medications during the pollen season and with an improvement in patients' quality of life. In some studies it was shown that the efficacy is dose dependant.[7-24] SCIT is also effective in allergic asthma. A Cochrane meta-analysis of 62 randomized controlled trials performed between 1954 and 1998 demonstrated a significant improvement in symptoms, a reduction in the use of rescue medication and an improvement in both allergen-specific and nonspecific bronchial hyperresponsiveness.[25] The results were consistent across the trials, although the methodological quality of the studies was, on average, low. An updated grading of the strength of the experimental evidence for SCIT and Sublingual Immunotherapy (SLIT) is provided in Table 70.1.

TABLE 70.1: Grading of the strength of the experimental evidence for SCIT and SLIT

	SCIT	*SLIT*
Clinical efficacy: Rhinitis	Ib	Ia
Clinical efficacy: Asthma	Ia	Ia
Clinical efficacy: Children (rhinitis)	Ib	Ia
Prevention of new sensitizations	IIb	III
Long-term effect	Ib	IIa
Prevention of asthma	IIb	IIb

Ia	Evidence from meta-analysis of randomized controlled trials
Ib	Evidence from at least one randomized controlled trial
IIa	Evidence from at least one controlled trial without randomization
IIb	Evidence from at least one other type of quasi experimental trial
III	Evidence from nonexperimental descriptive studies (comparative, correlation, case-control)
IV	Evidence from panels of experts or clinical experience or authorities

Long-Term Benefit (Carry-over Effect)

Allergen immunotherapy has been shown in several studies to maintain a long-term benefit after discontinuation. For example, in one DBPC withdrawal study, 3–4 years grass pollen immunotherapy was shown to result in sustained reduction in symptoms and rescue medication for at least three years following discontinuation.[26] Other studies have confirmed long-term benefit in relation to cat allergy, ragweed, tree pollen allergy and venom allergy. Immunotherapy has also been shown capable of reducing the onset of new allergen sensitivities in children.[3,4] In a prospective randomized controlled trial of pollen immunotherapy in children with seasonal allergic rhinitis, development of asthma was followed up over a period of five years. Two years following cessation of immunotherapy, there was a marked reduction in the risk of development of physician-diagnosed asthma (odds ratio 2.7, 95% confidence intervals 1.3–5.6) as compared to controls.[5] Taken together, these studies emphasize the important prophylactic value of injection immunotherapy, which is in contrast to pharmacotherapy where relapse of symptoms occurs immediately following discontinuation.

Safety

The major drawback of SCIT is the risk of potential side effects, like systemic allergic reactions, occasional anaphylaxis and even, fatalities. Risk factors for systemic reactions include extremely high sensitivity, coseasonal allergen exposure, history of previous systemic reactions and most importantly, the presence of uncontrolled bronchial asthma.[1,2]

Immunotherapy must be performed only under the supervision of a trained physician/specialist with a trained staff and adequate facilities available[1] with an appropriate observation area, facilities for vaccine storage at 4°C and access to the resuscitation facilities.[1,2] Immunotherapy protocols, in general, involve an updosing (induction) phase with weekly injections for 8–16 weeks, followed by a monthly maintenance injection (empirically this interval has been extended in some centers to 6–8 weeks). The maintenance phase should last 3–5 years. At each immunotherapy visit, it is recommended to record the date, dose and volume of allergen vaccine given. Adrenaline should always be available immediately. The patient should be observed for atleast 30 minutes following injections.

Injections should be postponed in the presence of respiratory infection, intercurrent illness, current asthma or symptoms due to concomitant allergen exposure. Dosage reduction, according to standard guidelines, should be performed in relation to previous systemic or large local reactions, during increased allergen exposure and if there is an extended time interval since the previous injections. In a randomized DBPC study with grass and birch vaccines, systemic mild reactions with SCIT occurred in 3.3% of the injections with grass and in 0.7% of injections with birch,[27] but no specific predictor could be identified. A postmarketing surveillance study reported a rate of mild-to-moderate level systemic reactions of 0.9% of the total doses given and of 3.7% of patients.[28] Another survey on grass pollen SCIT reports an occurrence of systemic reactions in 2% of patients,[29] with no life-threatening side effects. In a survey of more than 500 subjects, an occurrence of severe reactions was reported in 5.2% of patients and 0.1% of doses.[30] A retrospective study[31] in 65 patients receiving multiple vaccines and rush immunotherapy reported a 38% rate of systemic reactions with one severe episode. An e-mail survey involving more than 17,000 physicians reported a high rate of errors in administration (wrong patient or wrong dose),[32] which confirms the importance of careful administration of SCIT as recommended by international guidelines.[1,2,33] In general, according to USA surveys, fatalities occur in less than 1 case per 2,000,000 injections.[1]

Management of Adverse Events

Local swelling following injections is common and no treatment is required other than reassurance, although occasional use of an antihistamine may be indicated. Systemic reactions should be recognized and treated promptly, according to recommended guidelines. A grading system for systemic adverse reactions has been recently developed by World Allergy Organization (WAO), American Academy of Allergy Asthma and Immunology (AAAAI) and American College of Allergy, Asthma and Immunology (ACAAI).[34] In general, mild rhinitis or wheezing is treated by an antihistamine or bronchodilator, prolonging the observation period. More severe reactions, including moderate asthma, urticaria or angioedema require intravenous hydrocortisone and antihistamine. Adrenaline, 0.5 mg, by the intramuscular route, is indicated in rapidly evolving systemic reactions which do not respond to these measures and in all patients where there is associated moderate/severe respiratory impairment or hypotension. In general, if in doubt, give adrenaline which is more effective when administered early during a systemic reaction. Delayed systemic reactions are almost always mild, involving mild urticaria or asthma and respond to antihistamines and/or inhaled bronchodilator therapy.

THE SUBLINGUAL ROUTE

Starting from the beginning of 1900s, SIT was administered only subcutaneously, although various mucosal routes of administration were anecdotally proposed. When serious concerns about the safety of immunotherapy were raised, the clinical research with noninjection routes rapidly developed. Since its introduction in 1986, SLIT was regarded as a favorite alternative candidate to SCIT, especially due to its optimal safety profile.

After more than 20 years of clinical trials, postmarketing surveys and mechanistic studies, SLIT is nowadays considered a real step forward in the management of respiratory allergy, since it currently represents the only realistic alternative to the traditional injection route (Table 70.2).[35] The clinical efficacy (in term of symptom improvement) has been demonstrated for the most common allergens in more than 60 clinical trials,[36] and confirmed in meta-analyses in adult and pediatric populations.[37,38] Although meta-analyses have serious limitations, essentially due to the great heterogeneity of the clinical trials, so far they are the only instrument available for attempting to achieve an overall evaluation of the results of numerous trials according to

TABLE 70.2: Main characteristics of SLIT

Mechanisms	It is an allergen-specific immunomodulatory treatment which affects the Th2/Th1 balance and induces regulatory cytokines.
Association with drugs	SLIT does not replace drugs but must be used in association. On the long term period reduces the need for rescue medications.
Additional effects	Sustained efficacy after discontinuation, prevention of asthma onset.
Indications	Respiratory allergy (mite, grass, birch, olive, paritaria, cat).
Pharmaceutical forms	Available as drops, predosed dispensers, monodose vials, tablets.
Use	To be taken in the morning before breakfast. Keep under the tongue for 1–2 minutes then swallow. The first dose must be given under medical supervision.
Regimens	Updosing phase 10–30 days. Maintenance for 3–5 years daily or on alternate days according to manufacturer. Can be used also without an updosing phase. Preseasonal (stop at the beginning of the pollen season); coseasonal (start at the beginning of the pollen season); pre-coseasonal (start before the pollen season and stop at the end).
Side effects	Itching/swelling of the oral mucosa or tongue. Usually self-limiting in few days. Nausea or abdominal pain is rarer. Systemic side effects are rare. Only six cases of anaphylaxis described in 25 years.
Starting and duration	At least four weeks before the pollen season. For mites can be started in every period of the year. Duration 3–5 years.

evidence-based principles. Some concerns about SLIT still remain including the extent or magnitude of the clinical efficacy and the optimal maintenance dose to be used.

In addition, due to the large variability of the doses of allergen employed in many clinical trials[39] and to the various schedules of administration, SLIT is less rigidly formalized than SCIT. On the other hand, the recent large clinical trials conducted with grass tablets[40,41] have consistently shown the dose-dependency of the clinical effects of SLIT. This fact strongly increases the proof of efficacy, according to the GRADE recommendations.[42] Of note, in both those clinical trials, the magnitude of the effect over placebo largely exceeded the 20% suggested threshold, required for defining immunotherapy as clinically effective.[43] Finally, taking into account the economic aspects, which are of relevance in the case of AR, SLIT has been formally shown capable of reducing both the direct and indirect costs of the disease.[44-46]

It is also important to consider the effects of SLIT in a broader sense and now clinical data demonstrate the preventive effects of SLIT, in particular, in reducing the risk of inception of asthma in children with allergic rhinitis.[47,48] The most recent open controlled study[48] on this aspect, conducted in more than 200 children, receiving either SLIT or pharmacotherapy only for three years, showed a 40% reduction of the onset of persistent asthma in the SLIT-treated subjects, associated with a significant decrease of the onset of new sensitisations. Concerning the safety, the most common side effects are local (oral itching/swelling or nausea), but they are mild and self resolving in few days. The satisfactory safety profile (only six cases of anaphylaxis in 20 years) has suggested the possibility of avoiding the induction phase. In fact, the more recent large trials used a no updosing regimen. The good safety profile of SLIT in children, even below the age of 5,[49] gives the window of opportunity to use this treatment, taking advantage of the preventative effects.[50]

Despite the optimistic results of studies so far conducted, some important points still need to be addressed, including the optimal dose for each allergen and the optimal duration of a SLIT course needed to achieve the maximum benefits and the longest duration of the effects. In this context, recent large trials have started to provide some valuable information, at least for grass allergens, suggesting that[51] an eight-week preseasonal treatment achieves the best benefits. The preliminary results of a 15-years follow-up study reported that the optimal duration of a SLIT course should be four years.[52]

Mechanisms of SCIT and SLIT

Subcutaneous Immunotherapy (SCIT)

Subcutaneous immunotherapy is associated with a transient increase in allergen-specific IgE followed by blunting of seasonal increases in IgE. These effects are accompanied by increases in allergen-specific IgG4 antibodies.[53-56] Studies confirm and extend these observations to include measurements of the biological effects of IgG. These include the IgG-dependent ability of post immunotherapy serum to inhibit allergen-IgE complexes to B cells, the blocking of subsequent IgE-facilitated allergen presentation and activation of allergen-specific T lymphocytes and the prevention of allergen-IgE dependent activation of peripheral basophils.[57-59] SCIT is accompanied by inhibition of the recruitment and/or activation of effector cells including mast cells and eosinophils. Studies before and after SCIT confirm the reduction of the numbers of nasal mucosal eosinophils, basophils and mast cells during the pollen season,[60-64] a reduction in mucosal expression of the Vascular Adhesion Molecule (VAM) and decrease in IL-4 and IL-13.[65]

There is a blunting of allergen-driven Th_2 responses with reductions in IL-4, IL-13, IL-5 and IL-9[64,66-71] and an immune deviation to Th_1 responses with overproduction of IFNγ and/or the emergence of a population of regulatory T lymphocytes which produce the inhibitory cytokines IL-10 and/or TGF-β.[53-57,72] It is hypothesized that these regulatory T cells act directly to suppress allergen-specific Th_2 responses. Alternatively IL-10 is a known switch factor for IgG4 production,[73] whereas TGF-β favors IgA.[56]

Sublingual Immunotherapy (SLIT)

Sublingual immunotherapy is associated with qualitatively similar events to SCIT including modest increase in IgG, a transient increase in IgE and suppression of eosinophil recruitment and activation in target organs.[74-78] On the contrary, other studies failed to demonstrate changes in systemic T-cell and cytokine response[79,80] or local changes in T cells or effector cells within the sublingual mucosa. Some studies report an increase in IL-10 production[81,82] and another shows suppression of allergen-specific T cell responses after 12 months of grass therapy.[83,84] A recent study shows in vitro that SLIT reduces the expression of IL-5 and enhances the expression of IL-10 in PBMC stimulated with the allergen.[85] Further studies are needed to determine whether the same or alternative mechanisms are important for the effects of SLIT.

FUTURE DEVELOPMENTS OF SIT

The more and more detailed immunological knowledge and the concerns on the possible side effects of SCIT have prompted the development of new routes of administration and of modified vaccines. For instance, there is preliminary evidence that both the intralymphatic and the epicutaneous delivery of vaccines is effective and could represent an additional therapeutic option.[86,87] The introduction of recombinant allergens undoubtedly would allow a better standardization of allergen extracts, envisages the possibility of a tailored treatment according to individual sensitizations. However, at present, the few published trials of recombinant allergens for immunotherapy suggest that their clinical efficacy is not superior to that of traditional extracts.[88,89]

Another possible approach is the use of adjuvants to enhance TH_1 lymphocyte responses. Alum is the traditional adjuvant widely used in Europe. Alum has the effect of delaying absorption and in contrast to murine studies, downregulates Th_2 responses in humans, shown in both in vitro and in vivo studies. Bacterial adjuvants include lipopolysaccharide and DNA oligonucleotides. Monophosphoryl lipid A (MPLA), derived from the bacterial wall of Salmonella, is widely used as an adjuvant in prophylactic vaccines for infectious diseases and induces preferential Th_1 responses. An immunotherapy product with MPLA adjuvant was proven to be effective and is currently commercialized in Europe.[90] Bacterial DNA oligonucleotides containing an abundance of CPG motifs were shown to promote Th_1 responses and also induce IL-10, possibly by inducing T regulatory cells.[19] Preliminary data in humans from controlled trials support the use of these adjuvants in allergen extracts for treating respiratory allergy, but further studies are required, especially to rule out possible side effects.

The use of allergen-derived peptides for immunotherapy has the potential to stimulate "protective" Th_1 and/or T regulatory responses whilst avoiding systemic side effects associated with cross-linking of IgE on mast cells and basophils, which is the risk associated with conventional whole allergen extracts. Initial studies in cat allergy are encouraging, although, further studies are required.

CONCLUSION

Immunotherapy is an effective treatment for respiratory allergy. Since the 2001 ARIA document, new studies have enhanced the knowledge about this form of therapy. SCIT acts by either inducing immune deviation of T lymphocyte responses in favor of Th_1 responses to allergens and/or by the downregulation of Th_2 responses probably via regulatory T cells. IgG antibodies are also involved and have functional significance. The clinical efficacy of SCIT in allergic rhinitis and allergic asthma has been confirmed for most of the relevant allergens (grasses, trees, weeds, cats and mites).

SCIT is safe, provided that recommendations to minimize/manage adverse reactions are followed.

Several studies show the long-term efficacy of SCIT and the preventive effect on the onset of sensitization to additional allergens as assessed by skin testing. One study demonstrated that SCIT in children with pollen-sensitive rhinitis may reduce the risk of progression from allergic rhinitis to asthma. SLIT is effective in allergic rhinitis in adults and children.[83] One meta-analysis confirmed the efficacy also in asthma. Current data indicates that SLIT is safe and the rate of adverse reactions is not greater in children below 5 years of age. Further SLIT studies are needed to identify the optimal maintenance dose for all the relevant allergens and to elucidate the mechanism of action. Novel approaches for various other forms of allergen immunotherapy currently under evaluation include the use of adjuvants, peptides, recombinant/engineered allergens and DNA-conjugated allergens.

Allergen Desensitization

Vikram Jaggi

INTRODUCTION

The three main modalities of treatment of allergic diseases are avoidance, pharmacotherapy and immunotherapy. Avoidance of common allergens is at best difficult and at worst impossible. It has been often said that "asthma is neither curable nor preventable."[1] Harsh as this may sound, it is quite true. Pharmacotherapy is highly effective and predictable in most patients, but only for as long as it is being taken. This is true for both bronchodilators and for inhaled steroids. Immunotherapy fills the gaps left by avoidance and pharmacotherapy. It is the only treatment modality that has been shown to alter the natural history of asthma. It is often effective for years after stopping treatment. This has also been shown to prevent the development of asthma in patients with allergic rhinitis and to prevent the development of new sensitizations in patients with asthma. However, it is neither highly effective nor predictably effective in all patients.

DEFINITION

Allergen immunotherapy is the repeated administration of specific allergens to patients with IgE-mediated conditions, to protect against the allergic symptoms and inflammatory reactions associated with natural exposure to these allergens.[2] Other terms used for allergen immunotherapy include desensitization (which is almost never achieved), hyposensitization (which lacks specificity) and the lay terms "allergy shots" or "allergy injections." The currently preferred term is allergen immunotherapy, which is short, accurate and easily understood. From a humble beginning in 1911, when crude pollen extract were employed to treat seasonal allergic rhinitis (or hay fever),[3,4] it has come a long way and is now recognized as a scientific method to both treat patients with allergy and to prevent the progression of the "allergic-march." Allergen immunotherapy today would merit consideration in allergic rhinitis (both seasonal and perennial), allergic asthma, insect sting allergy (hymenoptera hypersensitivity) and in certain drug allergies.

For allergen immunotherapy to be successful, it is imperative that patient selection as clinically relevant and well standardized antigens should be used and mixing of too many allergens should be avoided. Only a trained and experienced physician should prescribe and practice immunotherapy.

To paraphrase William Osler, the father of American medicine, allergen immunotherapy is "an art based on science." The last decade has seen a vast accumulation of scientific evidence to support its use.

HISTORICAL BACKGROUND

There are accounts of "Vish-Kanyas" in the ancient Indian scripts where courtesan girls were given minute, but increasing doses of poison to render them immune to the lethal effects of the poison. Native American Indians were known to chew poison ivy to prevent severe skin rash or anaphylaxis. These were only practices based on observations; there was no scientific understanding or proof of how or why it worked. It was during 1910–1920 that immunotherapy found its roots in clinical practice. It was used first in allergic rhinitis and later in allergic asthma. It was thought at that time that subanaphylactic doses lead to "using up" or "exhausting" the antibodies responsible for causing allergy; although at that time IgE was unknown. IgE was discovered in 1965–1966, was later characterized and its role in type I hypersensitivity was elucidated.

In the last 15 years, there has been a vast accumulation of scientific evidence on the mechanisms and efficacy of allergen immunotherapy. The publication of the WHO Position Paper on Allergen Immunotherapy[5] in 1998 reaffirmed scientific faith in this time-tested treatment modality. Later, the Preventing Allergy Treatment (PAT) Study[6] showed that allergen immunotherapy could prevent the the development of asthma in patients with allergic rhinitis. PAT was an important prospective long-term (10 Years) study in children with allergic rhinitis: 205 allergic rhinitis patients in five European countries were given three years of subcutaneous immunotherapy and followed for a further period of seven years; 45% of children with allergic rhinitis not treated with imunotherapy developed asthma. The risk of developing asthma decreased by approximately 50% in the group of vaccinated children. This confirmed a long-held scientific belief that allergy vaccination early in the disease development could reduce the risk of the development of asthma in children suffering from allergic rhinitis.

MECHANISMS OF ALLERGEN IMMUNOTHERAPY

Asthma is a complex disease in which many cells and cellular elements play a role. The immune responses in asthma are skewed towards the abnormal TH_2 type responses and away from the normal TH_1 type of response. Immunotherapy is shown to lead to the complex series of changes in the cellular, cytokine and chemokine profile to steer the immune system away from the TH_2 response towards a TH_1 type of response.[7] The following changes in cells and mediators have been noted with successful immunotherapy:

1. *Allergen-Specific IgE:* In patients who receive allergen immunotherapy, initially there is an increase in specific IgE antibody levels followed by a gradual and sustained reduction in IgE levels.[8] Immunotherapy also blunts the seasonal increase in specific IgE levels that normally occurs due to seasonal exposure to the aeroallergens.[9] Consequent to the reduction in serum IgE levels, histamine release from the basophils and the mast cells is reduced.[10]
2. *Acute and Late Phase Reactants:* Allergen immunotherapy is shown to block both immediate- and late-phase allergic response.[11] It reduces the recruitment of mast cells, basophils and eosinophils in the skin, nose, eye and bronchial mucosa after provocation and after natural exposure to allergens.[12]
3. *Blocking Antibodies:* In successful immunotherapy, there is an increase in allergen specific IgA and IgG levels (particularly the IgG4 isotype). Allergen specific IgG induced by immunotherapy has been shown to "block" IgE-dependant histamine release and subsequent IgE-mediated antigen presentation to T cells.[13] However, there is a poor correlation between the rise in specific IgG levels and clinical improvement.[14]
4. *Interleukins:* There is an increased production of IL-12, a strong inducer of TH1 response.[15]

IL-10 is also increased. IL-10 reduces beta cell antigen specific IgE and increases the IgG4 levels, reduces proinflammatory cytokine release from mast cells, eosinophils and T-cells.[16]

Although the changes mentioned above are clinically measurable, the correlation between these change and clinical response is not consistent or strong. At present, these changes cannot be used to clinically monitor immunotherapy or its efficacy.[14]

Indications

There are three main indications for allergen immunotherapy (Table 71.1): Allergic rhinitis (both seasonal and perennial), allergic asthma and hymenoptera allergy. Randomized, prospective, double-blind, placebo-controlled studies have shown the effectiveness of allergen immunotherapy in allergic rhinitis and allergic asthma.[17,18]

Allergen immunotherapy will merit consideration in any patient who has natural aeroallergen exposure with the symptoms of upper and/or lower respiratory allergy

TABLE 71.1: Indications and contraindications of immunotherapy

A. Usual indications	Allergic rhinitis Allergic asthma Sting allergy
B. Usually not indicated	Food allergy Chronic idiopathic urticaria Angioedema atopic dermatitis
C. Caution required	Severe coronary artery disease Unstable angina Cancer unstable asthma Uncooperative patients Use of beta-blockers

symptoms with demonstrable evidence of specific IgE antibodies to the clinically relevant allergen(s). Allergen immunotherapy is recommended for patients who are unable to avoid the allergens (pollens or house dust mites for instance), have an inadequate response to avoidance and pharmacotherapy, have unacceptable side-effects of medicines or who do not wish to take noncurative medication indefinitely. The ideal candidate for allergen immunotherapy is the patient with moderate to severe rhinitis and mild to moderate asthma induced by a few selected seasonal or perennial allergens. In allergic rhinitis, the more severe the allergic rhinitis, the stronger is the reason to consider allergen immunotherapy. In asthma, on the other hand, severity is generally a reason not to consider allergen immunotherapy. Allergen immunotherapy in asthmatics should not be initiated unless the patient's asthma is stable with pharmacotherapy. Patients with severe or uncontrolled asthma are at an increased risk for systemic reactions to immunotherapy.[19]

Selection of Allergens for Immunotherapy

A carefully taken history, knowledge of local and regional aerobiology and corroboration with a properly performed Skin Prick Test (SPT) will guide the physician to select the relevant allergens to be included in the immunotherapy vaccine for a given patient. SPT information is to be interpreted judiciously with caution. The results are not to be taken at their face value. For most patients, it is possible to find out less than four or five important relevant allergens. If more than one pollen from the same family has tested positive, inclusion of only the representative, one of them would suffice. Cockroach and fungal antigens have the ability to cause proteolytic degradation of other allergens, particularly the pollens.[20,21] Hence, these should not be mixed. House dust mite antigen does not seem to have a similar deleterious effect on pollens, hence can be mixed with pollens.[22] A good allergy vaccine prescription should include comprehensive information (Table 71.2).

TABLE 71.2: Prescription requirements of a good, allergy vaccine

1. The relevant and confirmed allergens (not more than five usually; the lesser the better)
2. The starting dose (which is usually 0.1 ml of 1:5000 dilution w/v)
3. The projected therapeutic dose
4. The frequency of injections (usually once or twice in a week initially in the build-up phase, then fortnightly or monthly in the maintenance phase).

TABLE 71.3: Conditions which require a gradual doing schedule

1. The SPT has caused significant reactions
2. There is a history of anaphylaxis
3. There is a history of allergic reaction to allergen immunotherapy.
4. More severe forms of asthma
5. In the natural pollen season

Schedule

The general principle is to start a dilute dose, which is gradually built up in concentration to the dose that is maximally tolerated or which gives adequate clinical response (Build-up Phase). This dose is then continued initially weekly, then fortnightly and finally on a monthly basis for the maintenance phase. Certain patients would require a departure from this usual dosing schedule in that a more dilute dose is used initially and the increase in dose is more gradual (Table 71.3).

Delivery of Allergen Immunotherapy

The ideal venue for the allergen immunotherapy injections is the doctor's clinic. The doctor should be available at all times when the injections are being given. The staff giving injections should be suitably trained. A written informed consent of the patient should be obtained. The facility to store the vials at 4 degree centigrade should exist. A standardized color code and marking system of vials of different concentrations with the name of the patient should be clearly printed on it.

Measurement of Peak Expiratory Flow (PEF) should be done before the injection. A policy should be in place to either reduce or withhold the dose in case there is a significant (20-30%) fall in the PEF reading. Patient should be observed for 20 to 30 minutes after the injections. Resuscitation equipment, including adrenaline and oxygen should be available.

For the sake of convenience, the patient may take the injections from another physician near his home. This has been shown to be safe, provided all the prerequisites of safe immunotherapy mentioned above are met and are available there as well.[23] It is not advisable to take immunotherapy injections at the patient's residence.

Technique of Injections

The injections are given in the posterior portion of the upper 1/3rd of the arm where the deltoid meets the triceps muscle. Here the subcutaneous tissue is maximum. It is given subcutaneously (not intradermally or intramuscularly). The injections can be alternated between the two arms. After the injection, heavy exercise is to be avoided for one hour for this can lead to rapid absorption, which may precipitate a systemic allergic reaction.

Duration of Allergen Immunotherapy

Most patients, who show response to aeroallergen immunotherapy, demonstrate clinical improvement once the maintenance dose is reached in 6–9 month time. The response is maintained during immunotherapy. To prevent the relapse of symptoms on stopping allergen immunotherapy, it should be continued for three years in most patients.

After discontinuation, some patients experience sustained clinical remission while some relapse. At present there are no reliable or specific tests to predict as to which patient will relapse and which will maintain long-term remission after discontinuing effective immunotherapy. In a prospective controlled study, designed to look for the immunotherapy relapse rate during the three-year period after discontinuation of immunotherapy, 55% of 40 asthmatic patients who were treated with immunotherapy for 12–96 months, relapsed. The relapse rate was 62% in the group treated for less than 35 months as compared to 48% in the group treated for greater than 36 months.[24]

At the end of three years of effective immunotherapy, a decision has to be made whether allergen immunotherapy should be continued or stopped. The doctor and the patient should jointly decide keeping in mind the benefits and risks associated with continuing or discontinuing immunotherapy. Reasons to favor continuing immunotherapy are a good response to allergen immunotherapy; a maintenance dose of monthly injections; asthma rather than allergic rhinitis; and no major inconvenience to the patient of a monthly injection. Most patients who have benefited prefer to continue monthly immunotherapy. Reasons favoring a trial to stop allergen immunotherapy to see if remission is maintained are allergic rhinitis rather than asthma; less than optimum response to immunotherapy; and a major inconvenience of injections.

Efficacy

Many double-blind, placebo controlled, randomized clinical trials demonstrate a beneficial effect of allergen immunotherapy in the treatment of allergic rhinitis, allergic asthma and stinging insect hypersensitivity, it is effective in both children and adults.[17,18,25,26]

Bee Sting Allergy

Bee sting allergy is a “pure” reflection of a type I hypersensitivity reaction where allergy is demonstrated unequivocally to a single unambiguous allergen. Once the maintenance dose is achieved for venom immunotherapy, 80 to 98% of the individuals will be protected from a systemic reaction upon sting challenge. Allergen immunotherapy is generally given for five years for this indication. After discontinuation of allergen immunotherapy, the risk of a systemic reaction to sting is very low—about 10%.[25] The very high efficacy of allergen immunotherapy in bee sting allergy and its continued benefits even after stopping immunotherapy are good proof of the power of allergen immunotherapy per se, provided allergy is clearly demonstrated, a single allergen is incriminated and the vaccine is made using that single relevant allergen. This enhances confidence on the innate ability of allergen immunotherapy to be effective.

Allergic Rhinitis

The efficacy of allergen immunotherapy in allergic rhinitis has been clearly demonstrated in a large number of trials. These studies have shown significant improvements in symptoms, quality of life, medication use and in immunological parameters. Allergen immunotherapy is also shown to be beneficial for up to three to six years or more after completion of treatment. Allergen immunotherapy is shown to prevent the development of asthma in allergic rhinitis patients who receive immunotherapy.

Asthma

A Cochrane review of 75 trials with 3,188 patients revealed a significant reduction in symptoms and medication use and an improvement in bronchial hyperreactivity after immunotherapy.[18] Allergen immunotherapy also prevents the development of new allergen sensitization in monosensitized patients.[27]

Side Effects and Risks

There can be local and systemic side effects. Local reactions at the injection site, such as itching, redness and swelling are quite common. The patients in fact, welcome such reactions as an additional proof of allergy to that substance. They are generally less than 2–3 cm in diameter and subside on their own in a day. If

TABLE 71.4: Important reasons responsible for systemic reactions with immunotherapy

- Wrong dose or wrong injection
- Injection given at the height of the natural pollen season
- Uncontrolled asthma (FEV1 less than 70% of predicted)
- Patient on beta-blockers
- Patient having a natural exacerbation
- Injection from a new vial

troublesome, these can be managed by the local application of ice or with an oral antihistaminic. Such reactions generally do not require any reduction in the dose. Large reactions (greater than 2.5 cm) that occur repeatedly or after a day, may predict a more serious systemic reaction; a dose reduction to the previously tolerated dose may be required.

Systemic reactions in the form of increased upper or lower respiratory allergy symptoms, urticaria/ angioedema or hypotension can also occur rarely. A majority of such reactions occur within 30 minutes of the injection; hence the mandatory 30 minute waiting period in the clinic. Most of the reasons responsible for systemic reactions are predictable and avoidable (Table 71.4).

Very rarely, a severe reaction may occur in spite of all due diligence, due to the inherent high degree of allergic sensitivity. The physician must be prepared and equipped to handle these reactions. Systemic reactions are managed in the usual way with adrenaline, injectable antihistamine and steroid administration. Volume replacement is also required.

Fatalities during allergen immunotherapy, although extremely rare, are reported. There is no reliable data from India. The fatality rate in USA is one death per 2.5 million injections or an average of 3.4 deaths per year.[28] This has been constant on a per decade rate for the last three decades. Near fatal reactions, hypotension or respiratory arrest or both, are 2.5 times more common than fatal reactions.

Special Considerations in Various Patient Groups

Children Under 5 Years of Age

There have been reports of the efficacy of allergen immunotherapy in children of less than 5 years of age.[29] In children with allergic rhinitis, allergen immunotherapy might prevent the development of asthma.[30] Yet, most allergists hesitate to prescribe allergen immunotherapy to small children or toddlers for the following, very valid, reasons:

- Small children often outgrow their allergic symptoms on their own, as they grow older.
- The diagnosis of asthma sometimes cannot be made with confidence in a young wheezy child.
- Injections are traumatic to small children.
- Compliance with scheduled injections is not guaranteed in small children.
- Children may find it difficult to communicate the symptoms of impending allergic or anaphylactic reaction to allergen immunotherapy.

TABLE 71.5: Improvement in children following immunotherapy

1. Improvement in symptom control for asthma and allergic rhinitis.[30]
2. Increased PC_{20} to histamine.[31]
3. Decreased risk of development of asthma.[30]
4. Decreased development of new sensitizations.[32]

Older Children

Allergen immunotherapy in older children is effective and well tolerated. In general, the clinical indications are similar for adults and children. Recently, studies in children receiving allergen immunotherapy have shown improvement (Table 71.5). Most allergists agree that the response to allergen immunotherapy is better in children and young adults than in older adults.

Elderly Patients

Elderly patients generally respond less favorably to allergen immunotherapy. Further, presence of certain comorbid conditions like hypertension, coronary artery disease or cerebrovascular disease make them more prone to the risks of allergen immunotherapy. The fact that they may be taking beta-blockers may make resuscitation difficult if an allergic or anaphylactic reaction were to occur. However, elderly patients may also benefit therefore, age alone should not be the reason to deny allergen immunotherapy.[33]

Pregnancy

Allergen immunotherapy is effective in pregnancy. However, if an allergic or anaphylactic reaction occurs in pregnancy due to allergen immunotherapy, it could have serious consequences on the continuation of pregnancy. For these reasons, the general policy is:

- Allergen immunotherapy is not initiated in pregnancy.
- If allergen immunotherapy is being given and is well tolerated, it is not discontinued in pregnancy.
- If maintenance dose has already been reached, it is continued at the same dose.
- If maintenance dose has not been reached, dose escalation is generally not done during pregnancy.

Autoimmune Disorders

There are concerns regarding allergen immunotherapy aggravating autoimmune disorders by their uncertain effects on various parameters of immune modulation. These concerns are largely theoretical without any substantial evidence that such treatment is harmful in these diseases. Most allergists hesitate to prescribe allergen immunotherapy to patients with autoimmune diseases for the simple practical reason that the blame of even a spontaneous flare up, not uncommon in these diseases, would fall on immunotherapy if it happens during this period.

Sublingual Immunotherapy

The conventional route of immunotherapy has been through subcutaneous administration. Reports of an alternate (and a more convenient and safe) route, i.e. the sublingual route, appeared in literature, mostly from Europe, after 1985. This came to be called Sublingual Immunotherapy (SLIT), as opposed to conventional Subcutaneous Immunotherapy (SCIT).

Effectiveness of SLIT has been shown in both children and adults for both allergic rhinitis and asthma. It is effective against pollens (particularly grass pollen), house dust mites and cat antigens. It generally takes longer (1–2 years) before there is improvement in symptoms.[34] There is good theoretical support for the sublingual route for immunotherapy. The dendritic cells in the oral mucosa are different from he dendritic cells of the skin in that the oral dendritic cells have an increased expression of certain major histocompatibility complexes and costimulatory molecules, which make these cells particularly adept at antigen presentation. This may play an important role in directing subsequent immune effects.[35]

SLIT appears to a have a favorable safety profile as compared to SCIT. Local symptoms like itching and burning in the lips, tongue and mouth are common. Mild gastrointestinal symptoms are also commonly seen. Rarely, aggravation of rhinitis, or even more rarely of asthma symptoms may occur. Anaphylaxis is reported, but is extremely rare. No deaths have been reported so far.

SLIT is being widely used in Europe. There are a few questions, which remain to be answered before it is widely used:

The optimum dose and dosage schedules for each allergen need to be clearly defined. Moreover, trials with mixtures of antigens are required and long-term efficacy compared to SCIT remains to be seen. With growing experience, this has the potential for greater use in allergic rhinitis and asthma. Its major advantages are the obviously ease of administration (by the patient at the home), no waiting period in the doctor's clinic, very low incidence of side effects and lower costs.

There are many instances of poorly practiced immunotherapy, which need to improve (Table 71.6).

TABLE 71.6: Poor practices in allergen immunotherapy

1. Allergen immunotherapy being practiced by untrained or poorly trained physicians.
2. Immunotherapy being prescribed on the basis of serum specific IgE results without any correlation to clinical history.
3. Inclusion of too many antigens in the immunotherapy vaccine (many of them unnecessary or irrelevant).
4. Inclusion of more than one pollen of the same family where only one representative allergen would suffice.
5. Use of non-standardized allergens for allergy testing and vaccine preparation.
6. Allergens with ability to cause proteolytic degradation of other allergens (fungal spores and cockroach) being mixed with other allergens.
7. Maintenance dose that is too weak to give a full therapeutic response.
8. Immunotherapy, indiscriminately used in severe or chronic asthma with chronic airflow limitation where not much benefit is to be expected, but the risk of serious side effects is more.
9. Immunotherapy being used in conditions with no proven role: urticaria, angioedema, atopic dermatitis or food allergy.

FUTURE DIRECTIONS

Advances and improvements in allergen immunotherapy continue to occur. The existing practices of allergen immunotherapy need be optimized. The extracts to be used require standardization, at present only a few extracts are standardized. Today, it is possible to identify and monitor the chemical and cellular changes that occur with immunotherapy. The challenge lies in transforming this information into a clinically effective method of monitoring immunotherapy. Several approaches to modify immunotherapy have been tested, such as the use of allergoids, alum precipitates and most recently of peptides. Recombinant technology has provided a powerful technique both for sequencing proteins and producing allergens in commercial quantities. To reduce the risk of allergic reactions, recombinant protein can be modified so as to decrease the reactivity with IgE antibody while maintaining reactivity with T cells. The sublingual route of allergen immunotherapy is promising, likely to be more widely used.[36]

Bronchodilators

Samir Malhotra, Nusrut Shafique

INTRODUCTION

Treatment of asthma with bronchodilatory drugs has a long, fascinating history. Ancient ayurvedic texts recommended inhaled therapy particularly with steam, cinnamon, castor oil and herbs such as *Atropa belladonna, Datura stramonium* or mixtures containing anticholinergic compounds (like atropine, hyoscyamine and scopolamine). These compounds were also used by the ancient Greeks with the help of specially made inhaler devices. The first evidence for use of sympathomimetics drugs is available from the traditional Chinese medicine (Ma huang, from the plant *Ephedra sinica* containing ephedrine). Some of the other remedies tried before the modern era that might or might not have been effective include owl's blood in wine, opium-induced vomiting and chicken soup.

The treatment of asthma achieved a landmark in 1897 when John Abel was able to prepare crude adrenal extract (*epinephrin*). Subsequently, in 1920s and 30s, many epinephrine analogs were synthesized, including isoproterenol. However, its beta selectivity was not known. Its use became widespread only in the middle part of the 20th century. Development of isoprenaline in inhalational form was a big step, but tragically caused thousands of deaths during the 1960s. The discovery by Lands and coworkers of β_1 and β_2 receptors led to the development of salbutamol in 1967.

It is safe to assume that most of the world population consumes (and has consumed for hundreds of years) either tea or coffee/cocoa or cola drinks. Tea leaves (*Thea sinensis)* contain theophylline (small amount), caffeine, and theobromine; cocoa and chocolate seeds (*Theobroma cacao)* contain theobromine and some caffeine; coffee fruit (*Coffea arabica)* and the nuts of *Cola acuminata* contain caffeine. All these plant alkaloids are known to possess mood elevating, stimulant and bronchodilating properties. Although theophylline was first extracted in the 19th century, its use as bronchodilator was first described only in 1922.[1]

The next paradigm shift in the treatment of asthma came in the 1960s with the use of anti-inflammatory drugs. Khellin, a naturally occurring chromone (*Ammi visnaga* extract) had been used in Egypt and the Eastern Mediterranean countries for centuries in the treatment of respiratory diseases. The synthesis of *Cromolyn* (Roger Altounyan) in 1965 was an attempt to improve the bronchodilator activity and reduce the adverse effects of khellin. The Nobel Prize winning discovery of Kendall, Reichstein and Hench "relating to the hormones of the adrenal cortex," was soon followed by observations that adrenocorticotropic hormone and cortisol helped in asthma. As the use of corticosteroids in bronchial asthma was appreciated, the physicians started becoming more aware of their adverse effects, need for topical preparation was realized and inhaled steroids were introduced in 1972.

Bronchodilators are broadly classified as below:

- Beta-2 adrenergic agonists: Short acting, long acting and ultra long acting
- Methylxanthines
- Anticholinergic agents.

BETA-2 ADRENERGIC AGONISTS

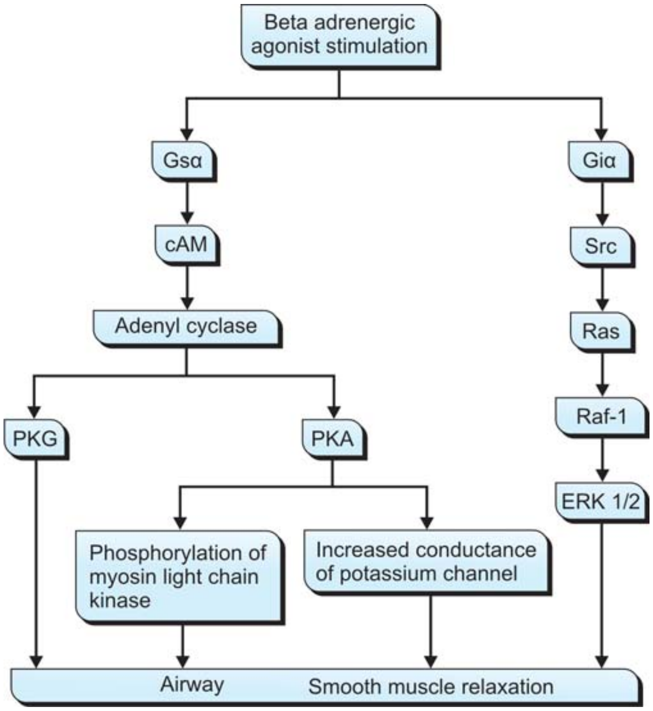
Beta-2 adrenergic agonists are the most efficacious and the most widely used bronchodilators. They can be used by inhalation or systemically, provide excellent smooth muscle relaxation and rapid bronchodilation with relatively few side effects, thus providing excellent risk-benefit ratio. The most preferred route when using these drugs is inhalational because the mast cells are located close to the airway lumen and more easily accessible to this route. However, less than 10% of the inhaled drug reaches the site of action, the remainder is swallowed. In order to reduce systemic adverse effects, the stress is on developing drugs that have low systemic bioavailability [poor absorption from the gastrointestinal tract (GIT) or high first-pass hepatic metabolism]. Another strategy is to increase the drug delivery to lungs and simultaneously decrease the amount of drug reaching the GIT; for example, by attaching a spacer to the Metered-Dose Inhaler (MDI).

Mechanism of action: Human lungs contain both alpha and beta adrenergic receptors; alpha receptors are not known to play any significant role in the regulation of the Airway Smooth Muscle (ASM) tone. On the other hand, beta adrenergic receptors, subtype-2, are the most important regulators of airway smooth muscle tone. Traditionally, the mechanism of action of beta-2 adrenergic agonists has concentrated on airway smooth muscle relaxation mediated through elevated cAMP levels (Fig. 72.1). Beta-2 agonists act through hetero-trimeric G-proteins leading to the stimulation of adenylyl cyclase. This in turn leads to the elevation of cAMP levels. Elevated cAMP activates Protein Kinase A (PKA). Activated PKA in turn phosphorylates myosin light chain kinase, thereby preventing airway smooth muscle contraction. While this concept still holds, several other mechanisms have been elucidated.[2] PKA may also bring about the activation of potassium channels leading to potassium efflux, which in turn causes hyperpolarization of airway smooth muscles. Cross activation of Protein Kinase G (PKG) may also lead to the relaxation of ASM.

Additionally, beta-2 adrenoceptors are expressed in inflammatory cells like mast cells, macrophages, neutrophils, eosinophils, as well as in type I and II alveolar cells. Activation of beta-2 adrenoceptors leads to the inhibition of these cells. This may additionally contribute to the benefits obtained with beta-2 adrenergic agonists.

Short-Acting Beta-2 Agonists (SABAs)

The agents of this group are used by inhalational route mainly. They are considered the most effective agents for relieving acute bronchospasm (Level A evidence). They are also indicated for preventing exercise-induced bronchospasm. Two epidemics of asthma deaths in the 1960s and 1970s in UK and New Zealand were attributed to the use of SABAs. Subsequently, the results of Mild Asthma Trial evaluated regular versus "as needed" albuterol in 255 patients with mild asthma.[3] Patients were randomized to 16 week treatment of "as needed" or regular use albuterol. Peak Expiratory Flow (PEF) variability, FEV_1, number of puffs of albuterol or symptoms were not different in the two groups. It was thus concluded that "as needed" therapy was preferable for the regular inhalation of bronchodilators. In a Cochrane review,[4] data from 31 outcomes were analyzable. There was little difference between the treatments for nearly all outcomes. In cross-over studies, evening peak flow was better with regular treatment. Bronchial hyperreactivity was slightly better in the "as needed" group. It was thus concluded that there was little advantage in using SABAs regularly.



Beta adrenergic agonist stimulation
Gsα
cAM
Adenyl cyclase
PKG
PKA
Phosphorylation of myosin light chain kinase
Increased conductance of potassium channel
Giα
Src
Ras
Raf-1
ERK 1/2
Airway Smooth muscle relaxation

Fig. 72.1: Molecular mechanism of action of beta-2 adrenergic agonists

If SABAs are needed more than twice per week, it is considered to indicate the inadequate control of bronchial asthma. Use of more than one SABA canister for quick relief of bronchospasm in a period of one month indicates an increased possibility of emergency department visit. Pharmacogenomics have thrown some light on the variability in propensity to deterioration of lung function while taking SABAs, albuterol in particular.[5]

Polymorphism of beta-2 adrenoceptor gene may explain some of this variability. Patients homozygous for arginine at position 16 are more likely to experience the worsening of lung functions than those who are either Arg/Gly or Gly/Gly genotype at the same locus.

a. Salbutamol: Salbutamol (albuterol) is the prototype SABA. It is given by inhalation, orally and parenterally (but not in all countries). The preferred route of administration is inhalation, even though only 10% to 20% of the administered dose reaches the site of action while the rest is swallowed or left behind in the device.[6] Salbutamol, unintentionally, but invariably swallowed from the inhaler device or taken orally as tablet, is readily absorbed from the GIT. Peak plasma levels (Cmax) are seen considerably earlier with inhaled formulation (Tmax 0.2 h) as compared to oral administration (Tmax 1.8 h).[7] Salbutamol undergoes considerable first-pass metabolism in the liver and gut wall, but not in the lung and has no active metabolites. Its plasma half-life is 4–6 hours as it is rapidly excreted, primarily in the urine. Its metabolism is stereoselective and levosalbutamol [*R*(–)-enantiomer] is metabolized about eight times more rapidly than the *S*(+)-enantiomer (also has no bronchodilator effect).[8] This property has been utilized to develop and market levosalbutamol as a novel drug (approved by the Food and Drug Administration in 1999), with some evidence of fewer adverse effects.

Adverse drug reactions: Tremors and nervousness are the most common adverse effects, they are dose-dependent and seen in up to 20% of patients. Headache (7%), palpitations, tachycardia (5%), muscle cramps (3%), elevated blood pressure, insomnia, restlessness, weakness, nausea, dizziness, and chest discomfort/heartburn are also observed. Throat irritation or sore throat and nosebleeds can also occur. Other rare adverse effects, which are occasionally seen are: Allergic reactions, rash, hives, throat irritation itching; difficulty in breathing; tightness in the chest; swelling of the mouth, face, lips or tongue; chest pain; ear pain; fast or irregular heartbeat; new or worsened troubled breathing; pounding in the chest; red, swollen, blistered or peeling skin; severe headache or dizziness; unusual hoarseness; and wheezing, swelling, bronchospasm or anaphylaxis (shock). Worsening of diabetes and lowering of potassium have been also reported. In a rare patient, inhaled salbutamol can paradoxically precipitate life-threatening bronchospasm.

Salbutamol should be given with caution in hyperthyroidism, myocardial insufficiency, arrhythmias, susceptibility to QT-interval prolongation, hypertension and diabetes mellitus. Hypokalemia should be kept in mind in severe asthma as the hypoxia associated with the condition and the concomitant drugs used in the situation may exacerbate hypokalemia. There are reports of abuse of salbutamol among both asthmatic and nonasthmatic (especially) young persons.

Drug interactions: Though pharmacokinetic interactions are not remarkable, pharmacodynamic interactions may be of concern. Concomitant use with other beta-2 agonists, corticosteroids, diuretics and xanthines may cause increased risk of hypokalemia. A propensity to cause hypokalemia increases the predisposition to digitalis induced arrhythmias. There may be adverse cardiovascular additive effects such as hypertension and tachycardia (if combined with tricyclic antidepressants or monoamine oxidase inhibitors). Similar interaction can occur with other stimulant sympathomimetic drugs, especially in patients with underlying coronary heart disease. Beta-blockers (especially nonselective) block salbutamol effects and bronchospasm may occur.

Use in asthma: For the relief of acute bronchospasm, 1 or 2 inhalations of salbutamol 100 mcg may be given from a conventional metered-dose aerosol as required, up to four times daily. Two inhalations may also be given just before the exertion for the prophylaxis of exercise-induced bronchospasm. Due to environmental concerns with the use of chlorofluorocarbons (CFC), CFC-free aerosols have been developed. These contain hydrofluoroalkanes (HFA). These are also available as dry powder inhalers. A dose, double to that of conventional aerosol is often required when the drug is administered in the powder forms. Long term use of beta adrenergic agonists is known to reduce the efficacy of the agents. This has been attributed mainly to the process of receptor desensitization. Uncoupling of the receptor from Gs, receptor internalization, upregulation of cAMP phosphodiesterase and down-regulation of Gs are some of the reasons for receptor desensitization.

b. Bitolterol: A long-acting beta-adrenergic agonist, it is the prodrug of colterol – a long-acting beta-adrenergic agonist synthesized mainly in the lungs. Although it has a long duration of action (>5 hours), unlike other long-acting beta-adrenergic agonists, it can be given for acute exacerbations of bronchospasm because of its rapid onset of action (about 2 minutes).

c. Orciprenaline: Also known as metaproterenol, it is less selective for beta-2 receptors than salbutamol, therefore causes more adverse effects. When given by inhalation, its onset of action is 30 minutes and duration 1 to 5 hours.

Because of its nonselective action, it has been used orally or by slow Intravenous (IV) infusion in the treatment of bradycardia (like isoprenaline).

d. Pirbuterol: It is a selective beta-adrenergic agonist with properties similar to that of salbutamol. The onset occurs in 10 minutes and the action lasts for 5 hours.

e. Terbutaline: Terbutaline is similar to salbutamol in most aspects except that its half-life is longer (16–20 hours). It is given mainly for the relief of acute exacerbations. It is available for inhalational, parenteral and oral administration.

f. Fenoterol: It has a rapid onset (5 minutes) after inhalation. It was implicated in the asthma-related epidemic (increased morbidity and mortality) in New Zealand in 1970s and 1980s with similar reports from Canada and Japan. Subsequently, a meta-analysis concluded that the increase in asthma-related mortality associated with beta-adrenergic agonist was only slight.[9] Moreover, the link between asthma-related deaths and fenoterol remained controversial as it was proposed that patients who used the drug had more severe disease.

g. Oral beta agonists: Oral preparations of beta-2 agonists have the disadvantage of a worse side-effect profile compared to inhaled preparations. A brief course of albuterol or metaproterenol syrup may be considered in the children of less than 5 years of age who cannot manipulate MDIs and yet have occasional wheezing. In occasional patients with severe asthma exacerbations, in whom the aerosol delivery causes worsening of cough and bronchospasm; oral forms of albuterol, metaproterenol or terbutaline may still be effective.

Long-Acting Beta 2-Adrenergic Agonists (LABAs)

Long-acting beta 2-adrenergic agonists as well as ultra long-acting agents are used for the maintenance therapy of asthma. The mechanism of action is similar to that of SABAs.

a. Salmeterol: This LABA (duration of action 12 hours) is used for maintenance therapy in conjunction with corticosteroids. The onset occurs at 10–20 minutes, but the peak effect is delayed making it unsuitable for the treatment of acute spasm. Publication of the results of interim analysis of Salmeterol Multicenter Asthma Research Trial (SMART) showed a small and significant increase in asthma-related deaths with the use of salmeterol, mainly in African-Americans.[10] A meta-analysis of 19 trials showed a similar increased propensity to cause asthma-related deaths, increased incidence of hospitalization due to asthma exacerbations and life threatening asthma attacks in those treated with salmeterol.[11] Therefore, the current practice in chronic asthma is not to use salmeterol as a substitute to inhaled steroids, but to add it to inhaled corticosteroid rather than increasing the dose of inhaled corticosteroid.

b. Formoterol: Formoterol is a partial agonist, touted for lesser propensity to desensitization of the beta-agonist activity. Experimental studies, however, have demonstrated that at equally effective doses, all beta-2 agonists may be equally susceptible to desensitization.[12] Like salmeterol, it has to be used in conjunction with corticosteroids. Addition of long-acting beta-adrenergic agonist to low or high dose of inhaled corticosteroids reduces the risk of asthma exacerbation compared to inhaled corticosteroid given alone. Inhaled formoterol is rapidly absorbed after inhalation. The plasma half life of the drug after administration is around 10 hours.

c. Bambuterol: Bambuterol metabolizes to terbutaline, the active metabolite. As result of slow metabolism, its approximate duration of action is around 24 hours. It may cause an increase in nonfatal heart failure in elderly patients.

d. Clenbuterol: It is used in the dose of 20 mcg twice daily, by inhalation. It is being widely abused by sportsperson for improving performance and also by farmers for improving the muscle mass of livestock. These effects remain unproven.

Ultra (Very) Long-Acting Beta-2 Adrenergic Agonists (ULABAs or VLABAs)

Attempts to further increase the duration of action of beta-2 agonists have been made so as to get compounds suitable for once daily administration, which by improving compliance, may also improve the outcomes. Most of these compounds are R,R-enantiomers of existing drugs since it is likely that these isomers will have less desensitization. Arformoterol, the R,R-isomer of formoterol has been shown to have duration of action of 24 hours. However, studies have also indicated that clinically important difference may not exist between the duration of action of formoterol and arformoterol. Carmoterol is another ultra long-acting beta-agonist with the structural elements of both formoterol and procaterol. In clinical trials, it has been shown to be as effective as formoterol, but is not yet approved. Clinical trials have also demonstrated safety and efficacy of another ULABA, indacaterol. It has, in addition to prolonged duration of action, a quick onset of action. Some of these agents are likely to be marketed soon. Many of the beta-2 adrenergic agonists are available as fixed dose combinations with inhaled corticosteroids while some are available as fixed-dose combinations with once-daily long-acting muscarinic antagonists (LAMAs).

Besides asthma, LABAs and ULABAs are being evaluated in Chronic Obstructive Pulmonary Disease (COPD) as well. It is an issue of concern whether LABAs may increase the mortality in COPD, in view of the result of the increased mortality seen in the SMART.[11] On the other hand, the landmark trial, Towards a Revolution in COPD Health (TORCH)[13] showed that there was a 17% relative risk reduction (amounting to 2.6% absolute reduction); in all-cause mortality. However, a combination of inhaled steroid (fluticasone) and a long-acting agent (salmeterol) was used in this large (> 6000 patients), multinational (42 countries), randomized trial. The combination improved lung function, reduced the total number of exacerbations and reduced the yearly rate of decline in FEV_1 more than the two individual drugs. Importantly, monotherapy with salmeterol had better survival than placebo, although statistical significance was not achieved.

METHYLXANTHINES (XANTHINES)

Theophylline, theobromine and caffeine are three important methylxanthines (some non-methylated xanthines are under development). Aminophylline (theophylline-diamine) is a commonly used derivative of theophylline. The exact mode of action of xanthines is not known. The primary action (although at high concentrations, *in vitro*) is through inhibition of Phosphodiesterases Group of Enzymes (PDEs), which in turn prevent breakdown of cAMP and cGMP, leading to their accumulation and effects such as relaxation of smooth muscle, stimulation of cardiac function, and inhibition of release of cytokines and chemokines (TNF alpha, leukotrienes).

Although xanthines are nonselective inhibitors of PDEs (of which at least five types are known), the enzyme most likely responsible for their action is PDE4 (to a lesser extent, PDE5), located on bronchial smooth muscle and inflammatory cells. Attempts to make selective PDE4 inhibitors (“designer xanthines”) have not been successful, the development of at least three selective PDE4 inhibitors (roflumilast, cilomilast and tofimilast) has been stopped due to various toxicities seen at low doses.

The second important mechanism of action of xanthines is through competitive inhibition of adenosine receptors. Adenosine can modulate adenyl cyclase activity, cause bronchial smooth muscle contraction and histamine release leading to bronchoconstriction. Although considered important by some, it must be mentioned that enprofylline (xanthine without adenosine antagonistic action) also has bronchodilator effect. Deacetylation of histones by xanthines may decrease the recruitment of histone deacetylases by corticosteroids to areas where the transcription of proinflammatory genes occurs. This can actually lead to synergism between steroids and xanthines, a theoretical interaction that now has some clinical evidence since theophylline was able to restore responsiveness to steroids in (smoker) asthmatics. In conclusion, xanthines have both bronchodilatory and anti-inflammatory effects, but which one is more important remains unclear.

The other effects of xanthines include Central Nervous System (CNS) stimulation (especially with caffeine), positive chronotropic and inotropic effects on heart, stimulation of gastric acid and intestinal enzyme secretion, mild diuretic effect (especially with theophylline), and stimulation of skeletal muscle (including the diaphragm) contraction.

Theophylline

It is the prototype drug of the class available for oral and parenteral administration. Dosage of modified release formulations should be titrated for an individual patient. Parenteral preparations are seldom used. Elimination is primarily hepatic, the metabolites as well as the unchanged drug (10%) are excreted in urine except in neonates (50% excreted unchanged). Its half-life in healthy, nonsmoking adults is seven to nine hours, and three to five hours in children and smokers, but higher (10–30 hours) in neonates, premature infants, elderly nonsmokers and in patients with liver disease or heart failure.

Solutions or uncoated tablets of theophylline produce maximal concentration in plasma within 2 hours. Sustained release preparations have marked interpatient variability in their bioavailabilities and may warrant careful dose titration. Food drug interactions are also highly variable. These agents are widely distributed, may cross placenta and pass into breast milk. Allopurinol, macrolides, quinolones, oral contraceptives and albendazole are known to decrease the clearance of theophylline, thus its dose need to be reduced. On the other hand phenytoin, ritonavir, rifampicin and sulfinpyrazone may increase its clearance.

Therapeutic Drug Monitoring (TDM) may be needed with its use, it being a narrow therapeutic index drug and having multiple interactions. An optimum therapeutic concentration is generally considered to be between 10–30 micrograms/ml. Toxicity has been seen with the rapid intravenous administration of therapeutic doses of aminophylline resulting in cardiac arrhythmias.

The adverse effects commonly encountered with theophylline and xanthine derivatives irrespective of the route are gastrointestinal irritation and stimulation of the CNS. Serum concentrations of greater than 20 mcg/mL are associated with an increased risk of adverse effects. Overdosage may also cause agitation, diuresis, repeated vomiting, cardiac arrhythmias, hypotension, electrolyte disturbances (such as hypokalemia, hyperglycemia, hypomagnesemia), metabolic acidosis, rhabdomyolysis, convulsions and death.

Aminophylline

It is a prodrug of theophylline (joined with ethylenediamine), releases theophylline *in vivo*. It is given slowly intravenously by slow injection (or infusion) in acute severe bronchospasm, at a rate greater than 25 mg/minute. It is important to elicit drug history of the patients before the administration of intravenous aminophylline. In patients already on xanthine medication, it is safe to omit the loading dose or if possible, serum concentration estimated and the required dose calculated. It is also administered orally and rarely, rectally absorption from the latter route is erratic. Besides asthma, it is also used in the management of COPD, neonatal apnea and erectile dysfunction (local application). It has been also tried in motor neuron disease, methotrexate-induced neurotoxicity, and for removal of fat (locally).

Diprophylline

Unlike theophylline, diprophylline is largely cleared unchanged renally (half-life 2 hours) and does not need dose modification in patients with hepatic dysfunction. Unlike theophylline, drug interactions are uncommon. It is used in doses of 15mg/kg, three to four times a day.

Caffeine

Caffeine is a xanthine that is more widely acknowledged as a CNS stimulant. It increases alertness and reduces sleep. In doses of 5–10 mg/kg, it has a bronchodilator action that is weaker (40%) compared to theophylline, which is why it is hardly used in asthma.

Xanthines (particularly theophylline and aminophylline) were used as first-line bronchodilators in the past, but their position was taken by steroids and beta-2 agonists. Xanthines are less efficacious and have greater potential for adverse effects. There has been a resurgence of their use for their anti-inflammatory properties and because of the availability of slow-release preparations for nocturnal control.

ANTICHOLINERGIC AGENTS

Airway smooth muscles express both M2 and M3 muscarinic receptors. Besides in airway smooth muscles, muscarinic receptors are also present in glandular and surface epithelial cells, endothelial cells and various inflammatory cells in the airway. Acetylcholine produces bronchoconstriction predominantly by acting through M3 muscarinic receptors. Activation of these receptors leads to the activation of Phospholipase C (PLC) resulting in the formation of IP3 and DAG. Additionally, M2 receptors augment the contractile response mediated by M3 receptors. This is achieved by limiting adrenergic relaxation and inhibitory effects on calcium-activated potassium channels. M3 receptors are also involved in the stimulation of mucus secretion from submucosal glands and goblet cells.

There are several reviews on the usefulness of anticholinergics in acute and chronic bronchial asthma in children and adults. Mostly, it is shown that while the agents are useful in acute asthma, there is insufficient evidence for their role in chronic asthma.[14-17] Specifically, they were shown to cause significant reductions in hospital admissions with favorable symptom scores, particularly in the respect of daytime dyspnea and daily peak flow measurements. For the latter, the clinical significance was small and in terms of peak flow measurements, equated to approximately a modest 7% increase over placebo. The more clinically relevant comparison of a combination of anticholinergic plus SABA versus SABA alone gave no evidence in respect of symptom scores or peak flow rates of any significant differences between the two regimes. Thus, these drugs may be used to provide additive benefit to SABA in moderate-to-severe asthma exacerbations or may be used as alternative bronchodilators for patients who do not tolerate SABA.

Ipratropium Bromide

It is a quaternary ammonium antimuscarinic agent. When given by inhalation, it causes direct bronchodilatation. Ipratropium bromide provides additive benefit to SABAs in moderate-to-severe asthma exacerbations, leads to somewhat higher and prolonged effect compared to either agent used alone. It may also be used as an alternative bronchodilator for patients who do not tolerate SABAs. When ipratropium is used alone, the bronchodilation by onset is slower, the magnitude is lesser and more variable as compared to SABAs. The exact cause of variability in response to ipratropium is not known, may be related to the intrinsic parasympathetic tone in a particular patient as well as the contribution of parasympathetic system in causing bronchoconstriction.

Ipratropium is used by the inhalational route; 10% to 30% of the drug is deposited in the lungs, very small amount reaches the systemic circulation as it is not absorbed from the GIT. It is available as metered-dose inhalers (alone and in combination with beta-2 agonists), dry powder capsules and as nebulizer solution. The usual dose from an MDI is 1 or 2 inhalations (20–40 mcg) three or four times daily, but the total daily dose should not exceed 12 inhalations. Inhaled antimuscarinics have greater usefulness in COPD. Intranasal ipratropium is also used in the management of rhinitis (reduces rhinorrhea and sneezing).

Being an anticholinergic, it is associated with the dryness of mouth, constipation (rarely paralytic ileus), tachycardia, palpitations and arrhythmias. Rarely, it can cause urinary retention (especially in the presence of prostatic hyperplasia) and precipitation of angle closure glaucoma. Patients with glaucoma should be advised to be careful while using these agents to avoid the mist entering the eyes. Antimuscarinics cause impaired drainage of aqueous humor while beta-2 agonists increase the production of aqueous humor; their concomitant use (which is routinely done) may be potentially harmful in susceptible patients. Rarely, paradoxical bronchospasm (seen also with other bronchodilators, may be attributable to some preservative) and hypersensitivity reactions (urticaria, angioedema, rash and anaphylaxis) have been reported. There is some evidence of increased mortality in COPD seen with ipratropium while not seen in others.[18-20]

Tiotropium Bromide

It is a long-acting quaternary ammonium anticholinergic agent (duration of action 24 hours) available for aerosol administration. About one-fifth reaches systemic circulation after dry powder inhalation and about one-third after inhalation of the solution. Its half-life is five to six days, excreted by the kidneys and therefore its use in patients with renal impairment, especially if creatinine clearance is < 50 mL/min, should be avoided.

It should not be used for the initial treatment of acute bronchospasm, primarily used in the maintenance treatment of COPD, as well as of asthma. It is used once daily as two inhalations of 2.5 mcg from the MDI. Besides the adverse effects seen with other antimuscarinics, pharyngitis, sinusitis, rhinitis and epistaxis have been reported. Recently, a small increase in the risk of stroke (8 per 1,000 patients treated for one year compared with 6 per 1,000 patients on placebo) has been seen.[21] There have been case reports of dermatological adverse reactions such as cutaneous lupus and photosensitive lichenoid eruption.

Recent advances in anticholinergics have focused on the development of agents with lower systemic absorption and thereby having lesser adverse drug reactions, as well as on oral formulations. Aclidinium bromide is a long-acting anticholinergic agent selective for M3 receptors. The drug is being evaluated mainly for COPD and was shown to have bronchodilator effect lasting for 24 hours in healthy volunteers challenged with methacholine.[22] With better efficacy observed when anticholinergics are used in conjunction with beta-adrenergic agonists, certain fixed-dose combinations have been recently approved, several others, particularly with tiotropium, are under development.

Patient Education in Asthma

Bharat Bhushan Sharma, Virendra Singh

INTRODUCTION

With the availability of inhaled and modern means of therapy now, we have effective treatment options to reduce agony of asthmatic patients. Inspite of effective therapy for diseases such as asthma, many patients still suffer due to ignorance, lack of understanding and faulty perception of the disease. Patient education is the only means, which can impart skills to enable a patient to use modern therapy and to remove wrong notions. Patient education is an integral part of the treatment in almost all respiratory diseases, but its efficacy in evidence-based medicine is proved mainly in asthma. Patient education is also important for risk factor reduction, especially for the quit-tobacco plan. It is an essential component of respiratory rehabilitation, for example in patients with Chronic Obstructive Pulmonary Disease (COPD).

Recent guidelines have contributed significantly in the elucidation of this question in the terms of sound evidence base.[1,2] In patients with COPD, rehabilitation has been recognized as an established modality of treatment as it can increase functional capacity, lead to improvement in dyspnea and quality of life.[1] The role of rehabilitation in other respiratory disorders is gradually being scrutinized, however, further evidence is needed to have clear guidelines. (See chapter on Rehabilitation for more details).

Patients must become effective partners in their own care, for the treatment of a chronic respiratory disorder to become successful. Patient education in asthma is well supported by evidence based documents almost similar to the effectiveness of respiratory rehabilitation in COPD patients.[3] Asthma is one disease which starts in childhood and continues throughout life with marked fluctuations in severity. When a patient is sick, even to take a breath becomes a mounting task. In contrast, during symptom-free period, a patient considers himself as fit as a normal person. Patients must make day-to-day or even moment-to-moment decisions, in response to such fluctuations, mainly regarding self-medication or to ask for medical help. Factors like patient motivation, literacy and socioeconomic setup markedly influence such decisions.

Education need of the asthmatic patient, which often remains neglected by health care providers, is no less important than that of patients with coronary artery disease or diabetes mellitus. Asthma education is commonly practiced in the western countries, but there are hardly any organized asthma education programs in India except for the availability of some expert documents and reports on efficacy of asthma education.[4-7]

GOALS OF ASTHMA EDUCATION PROGRAMS

The primary aim of asthma education is to keep the patient well and to impart ability to adjust the doses of the medicines according to an action plan. Reducing the costs is the primary aim for the health care services. The Global Initiative for Asthma (GINA) treatment has recommended the following issues for discussion with a patient:[3]

- Asthma is a continuous disease
- Patient’s expectation from treatment
- Patient’s fears and apprehensions about asthma.

To achieve these goals, specific information with a practical goal should be given to change behavior. Teaching over several days, covering many general topics may not be as useful as regular review of basic principles. Frequent verification of understanding and application of learned behavior are important.

BENEFITS OF ASTHMA EDUCATION PROGRAMS

One of the earliest published, randomized clinical trial of an education program for patients with asthma was a study in 1973 which included adult, inner-city residents. Members of the treatment group participated in a single, small-group session. This project had led to conclusions, which have now become the mainstay of planning and evaluation in patient education and health promotion.[8] The model recognizes three sets of variables that must be considered in determining the type of educational interventions:

1. *Predisposing factors:* The knowledge, attitudes, beliefs, and perceptions make up a baseline on which an action can take place.
2. *Enabling factors:* Skills and resources required to be able to enact a motivated behavior.
3. *Reinforcing factors:* Make the behavior more or less likely to be repeated or sustained over time. This has led to popular concept of precede-proceed framework.[9]

Some of more recent studies underline the importance of behavioral change over education alone.[10] However, the main draw back of systematic reviews in the asthma education is the variability between the study interventions and their insufficient documentation, which requires a more uniform and standard approach in these studies.[11,12]

The recent National Asthma Education and Prevention Program (NAEPP) guidelines gave an evidence grade of A to the recommendation for asthma self-management education.[13] Asthma education should be provided at every patient encounter by all providers and at all points of care (evidence grade B). The guidelines also recommend written action plans that include specific treatments and actions to respond to changes in symptoms, especially for patients with moderate-to-severe asthma (evidence grade B).[14,15]

Several adult asthma education programs have also reported better correlation between knowledge and outcome. A Cochrane review of 36 trials that compared usual care to self-management plus regular review and an action plan found more regular physician visits, fewer emergency department visits, slightly better lung function and peak flow measurements, need of fewer drugs and rescue medication in later group.[16] Studies that involved less intensive interaction and monitoring, had less effect while written action plans had better outcomes.[17]

TABLE 73.1: Methods and benefits of asthma education[3,13]

Methods	*Improvements*
Small group sessions	Knowledge of asthma
Individual teaching	Feelings of control
Large group lectures	Positive attitudes
Problem-solving sessions	Physical activity
Booklets	Inhaler technique
Diaries	Use of peak flow meters
Computer games	Peak flow rates
Promotion of peak flow monitoring use	Asthma severity
	Reduction of school absenteeism
Repeated audits	Health care costs
Checklists	Emergency room visits/ hospitalizations

METHODS AND SETTINGS

Methods

No single teaching method or medium will work for all patients in all settings (Table 73.1). Many factors will influence the selection of methods. Written material allows the patients to understand information at their ease, and is on hand for future reference. Interactive computer programs are somehow individualized in approach and many are available on the Internet.[18] Videotapes are attractive for patients, but have the limitation of not being individualized. Utility of videotapes and other material ultimately depends upon individualized counseling, either in a one-on-one or group setting.

Settings

There is evidence of positive asthma-education outcomes in multiple settings.[19] Settings that provide follow-up visits, education-reinforcement and continuing asthma monitoring are associated with better asthma control. The NAEPP guidelines recommend asthma education at all points of care, so that the patient has multiple chances to learn about asthma and build up self-management skills.[13] It is quite interesting that the clinic setting would allow the best opportunity for an ongoing collaborative relationship between the patient and the provider, and better outcomes (evidence grade A).

Asthma education in the school is important because of the potential for reaching a large number of children. Comprehensive school-based asthma programs can improve symptom control and reduce acute-care utilization.[20,21] Home-based education programs can significantly impact allergen control (evidence grade A).[13] Decreasing allergen exposure reduces exacerbations, and should be a component of asthma education when allergens are an important trigger.

ASTHMA EDUCATION PROGRAM COMPONENTS

The written action plan is the single most important strategy of asthma education. Patients who recognize asthma symptoms, understand peak flow measurements and how to respond appropriately are more likely to maintain asthma control. The NAEPP guidelines include example action plans.[13]

What should be the content of asthma education?

Patient is educated to impart skills in following aspects of asthma:

- Diagnosis
- Inhaler medicines
- Difference between reliever and controller drugs
- Potential side effects of medicines
- Control of symptoms
- Early detection of exacerbation
- Monitoring control of asthma
- How and when to take medical assistance?

The two main components of asthma, i.e. inflammation and bronchoconstriction should be made clear to the patients. The differences between smooth muscle contraction and the inflammatory components should be explained with the use of figures. The patient must be able to distinguish between reliever (bronchodilators) and controller (anti-inflammatory) agents. They also should know that reliever act rapidly, but controller-steroids work more slowly. Importantly, patients must understand that the controller drugs will allow asthma control to be achieved and must be taken regularly instead of "on demand" basis.

The use of beta 2-agonists before exercise, exposure to irritants and cold air, should be suggested. Inhaler technique should be demonstrated and checked regularly, as should the use of spacer devices or dry powder inhalers. The key to achieving asthma control is the patient's understanding of what are the criteria of control or of loss of control of asthma, and how to monitor severity according to symptoms and expiratory peak flow rates.[22] Peak Expiratory Flow (PEF) monitoring may be beneficial because of the learning and reinforcement value of self-monitoring and the greater sense of control and self-efficacy that comes with self monitoring.[23]

After establishing the goals of therapy, corresponding symptom and peak flow end points, patients must know how to adjust medication and when to seek medical care according to the symptoms and PEF, using their action plans instead of relying solely on their physicians. Action plans have been developed and seem to reduce morbidity significantly, although it is difficult to dissociate their effects from treatment adjustments and other aspects of the education program.

Asthmatic patient should also receive general counseling about nutrition, sleep habits and relaxation methods, and they must have an opportunity to ask questions of general relevance to asthma management.

How to assess adequacy of teaching and understanding?

Evaluation can be made immediately after the teaching session by a questionnaire incorporating key issues. The level of confidence of the patient does not necessarily mean level of understanding of asthma management. The level of the control of asthma achieved, health services use (emergency visits, hospitalizations), quality of life evaluation of the asthmatic, and the level of airflow obstruction are useful parameters to determine long-term benefits of asthma education.[24] Overall assessment may be repeated after a few weeks, and then at intervals of three to six months.

PATIENT EDUCATION: PROBLEMS

Among the barriers to effective asthma education, one must include the limited time available for teaching in the physician's office, the use by physicians of terms that the patient does not understand, the tendency of medical personnel to concentrate on acute treatment instead of long-term control, and until recently, the fact that treatment emphasized symptomatic relief and not prolonged control of airway inflammation. Patients often report that it is difficult to discuss their illness during a hurried medical consultation, they may be embarrassed to ask questions, and likely to forget or confuse multiple recommendations if they are not written (Table 73.2).

Other problems relate to the acceptance and the understanding of asthma. As with other chronic diseases, there is often an initial denial of the problem; efforts should be made to help the asthmatic accept his condition, a prerequisite to effective control. False

TABLE 73.2: The barriers to effective asthma education [6,13]

Physician related

- Limited time available for teaching patients
- Use of terms that the patient will not understand
- Tendency to concentrate on acute treatment instead of long-term control.

Patients related

- Difficult to discuss their illness—hurried consultation, embarrassed to ask questions
- Likely to forget or confuse multiple recommendations if they are not written
- Problems with acceptance and understanding of asthma
- Misunderstanding the fundamental principles
  - Inadequate perception of symptoms, leading to non-application or delay in the application of principles taught
  - Inadequate perception of signs, e.g. misinterpretation of changes in peak flow
- False expectations and a desire to be “cured”
- Abrupt cessation of the medication. The patient should be advised stepping down instead of stopping suddenly
- Preconceived assumptions, fears and concerns, e.g. fear of steroids.

expectations are frequent. A desire to be cured may push patients to try different forms of treatment that offer a miraculous cure (e.g. popular fish therapy of South India). The importance of regular treatment, even when asthma is apparently controlled, is often not understood, leading to gross undertreatment.[25] Preconceived assumptions, fears and concerns, e.g. fear of steroids, and inadequate counseling from misinformed sources may also interfere with teaching.

CONCLUSION

Effective respiratory rehabilitation incorporates exercise schedules and patient education comprehensively to encompass treatment and other aspects needed to make any individual patient recover gradually from the deterioration of the condition and to remain in a fully functional state as far as possible. Patient education is one of the major components of asthma treatment and prevention. A variety of teaching programs have been developed to improve self-management skills. An action plan that incorporates objective measurements like peak flow has been more successful in improving control and reducing morbidity than that based on the improvement of only knowledge. Such measures are aimed at specifically preventing needless delays in treating exacerbations and improving compliance with preventive measures.

Childhood Asthma

Meenu Singh

EPIDEMIOLOGY

Bronchial asthma is the most common chronic disease of childhood, affecting an estimated 6 million children. The burden of asthma affects the patients, their families, and the society in the terms of loss of work and school days, lessened quality of life, avoidable emergency department visits, hospitalizations and deaths. Improved scientific understanding of asthma has led to significant improvements in asthma care. The International Study of Asthma and Allergies in Children (ISAAC) study noted a significant variation in its prevalence in different parts of India with a range of 0.5% to 18% in a 12-month prevalence of self-reported asthma symptoms from a written questionnaire.[1] A 20 to 60 fold difference in the prevalence of symptoms was found between various centers involved in this study.

Although prevalence data of allergic disease in India is scarce, the little data that is available suggests that the patterns differ in different areas.[1-4] A study of 271 children from rural areas of Tamil Nadu reported a prevalence of breathing difficulty at any time in the past in 9%.[5] In the study from rural areas of North India, the prevalence of chronic cough among children aged 1–15 years (n = 2275) was 1.06%, and two-thirds were due to asthma.[3] Such variable patterns also exist across urban regions. Prevalence rates ranging from 1.9% to 15.7% have been reported. Such national variation, with almost 10–15 fold difference in the prevalence of allergic disorders, is probably unique to India. In a recently conducted study at our center under the aegis of the Asthma Task Force of the Indian Council of Medical Research, a survey was conducted on 10,028 school children (10–15 yeas of age) belonging to 39 randomly selected schools for the diagnosis of asthma and other atopic disease in Chandigarh. A total of 536 children were found to have a current clinical diagnosis of asthma, allergic rhinitis or eczema with a 3.3% prevalence of asthma. These findings were similar to those of ISAAC surveys conducted earlier at our center.

The comparative prevalence of wheeze in 13–14 year olds between the two South Asian cities (Galle, Sri Lanka and Chandigarh, India) representing each of the above archetypes has been studied.[5] The validated one page ISAAC questionnaire for 13–14 year olds was used for the study. Crude prevalence rates and odds ratios [with 95% two sides Confidence Intervals (CI) for the comparison of prevalence rates] were calculated. The prevalence rate for wheezing in Galle (28.7%) was higher than that of Chandigarh (12.5%). The Odd Ratios (ORs) for prevalence for Galle versus Chandigarh were: 2.3 (95% CI 1.8–2.9) for lifetime wheezing; 2.1 (95% CI 1.6–2.7) for wheezing in the previous year; 4.8 (95% CI 3.5-6.7) for exercise-related wheeze; and 1.7 (95%CI 1.2–2.3) for physician diagnosed wheeze, thus demonstrating significant differences in wheeze prevalence between the two cities ($P < 0.05$). The numbers of 13–14 year olds experiencing less than 12 wheezing episodes per year or sleep disturbance due to wheeze of less than one night per week were also significantly higher for Galle. Hence, a higher prevalence of wheeze was noticed in 13–14 year old children living in an old-fashioned, congested city (Galle) than in a clean city, Chandigarh.

DEFINITION

Clinically, asthma is a complex disorder characterized by variable and recurring symptoms, airflow obstruction, bronchial hyperresponsiveness and an underlying inflammation. The interaction of these features determines the clinical manifestations and severity of asthma and the response to treatment.[6,7]

Asthma is a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role: In particular, mast cells, eosinophils, neutrophils, T lymphocytes, macrophages and epithelial cells. In susceptible individuals, this inflammation causes recurrent episodes of coughing, particularly at night or early in the morning, wheezing, breathlessness and chest tightness. These episodes are usually associated with widespread, but variable airflow obstruction that is often reversible, either spontaneously or with treatment.

PATHOPHYSIOLOGY

Airflow limitation is caused by a variety of changes in the airway, all influenced by airway inflammation:

- Bronchoconstriction: Bronchial smooth muscle contraction that quickly narrows the airways in response to exposure to a variety of stimuli, including allergens or irritants.
- Airway hyperresponsiveness: An exaggerated bronchoconstrictor response to stimuli.
- Airway edema: As the disease becomes more persistent and inflammation becomes more progressive, the presence of mucosal edema, mucus hypersecretion and the formation of inspissated mucus plugs further limit airflow.

Reversibility of airflow limitation is incomplete in some patients. Persistent changes in airway structure occur, including sub-basement fibrosis, mucus hypersecretion, injury to the epithelial cells, smooth muscle hypertrophy and angiogenesis. Recent studies provide insights into different phenotypes of asthma that exist. Different manifestations of asthma may have specific and varying patterns of inflammation (e.g. varying intensity, cellular mediator pattern and therapeutic response). Further studies will determine if different treatment approaches benefit the different patterns of inflammation.

Immunobiology of Asthma

Airway obstruction in asthma is mediated by hyperresponsive bronchial smooth muscle, secreted airway glycoproteins, and inflammatory debris produced by airway goblet cells and other cells, as well as edema or swelling of the airway wall. The development of asthma involves the interplay between the host factors and the environmental exposures that occur at a crucial time in the development of the immune system. Genetic susceptibility also plays a crucial role in this interaction. A definitive cause of the inflammatory process leading to asthma is not yet established.

a. *Innate Immunity:* Numerous factors may affect the balance between Th1-type and Th2- type cytokine responses in early life and down-regulate the Th1 immune response that fights infection. Instead there is dominance of Th2 cells leading to the expression of allergic diseases and asthma. This is known as the "hygiene hypothesis," which postulates that certain infections early in life; exposure to other children (e.g. presence of older siblings and early enrolment in childcare, which have greater likelihood of exposure to respiratory infection); less frequent use of antibiotics, and "country living" are associated with a dominant Th1 response and lower incidence of asthma. On the other hand, the absence of these factors is associated with a persistent Th2 response and higher rates of asthma.

b. *Genetic Factors:* Asthma has an inheritance component, but the genetic factors, which are involved, remain complex. As the linkage of genetic factors to different asthma phenotypes becomes clearer, treatment approaches may become more directed to specific patient phenotypes and genotypes.

c. *Environmental Factors:* The two major factors that are important in the development, persistence and possibly the severity of asthma are:
    i. Airborne allergens (particularly sensitization and exposure to house dust-mite and Alternaria), and
    ii. Viral respiratory infections [including Respiratory Syncytial Virus (RSV) and rhinovirus].

    Other environmental factors under study are:
    i. Tobacco smoke (exposure "*in utero*" is associated with an increased risk of wheezing, but it is not certain that this is linked to subsequent development of asthma).
    ii. Air pollution (ozone and particular matter).
    iii. Diet (obesity or low intake of antioxidants and omega-3 fatty acids).

The association of these factors with the onset of asthma has not been clearly defined. A number of clinical trials have investigated dietary and environmental manipulations, but the trials have not been sufficiently conclusive to permit recommendations.

Knowledge of the importance of inflammation central to the pathogenesis of asthma continues to expand and underscores inflammation as the primary target of treatment. Numerous studies indicate that current therapeutic approaches are effective in controlling symptoms, reducing airflow limitation and preventing exacerbations, but currently available treatments do not appear to prevent the progression of asthma in children. As the various phenotypes of asthma are defined and inflammatory and genetic factors become more apparent, new therapeutic approaches will be developed that may allow more specific treatments to the individual patient's needs and circumstances.

DIAGNOSIS

To establish a diagnosis of asthma, the clinician should determine that symptoms of recurrent episodes of airflow obstruction or airway hyperresponsiveness are present; airflow obstruction is at least partially reversible; and alternative diagnoses are excluded.[7]

Key Symptom Indicators for Considering a Diagnosis of Asthma

The presence of multiple key indicators increases the probability of asthma:

- Wheezing is a high-pitched whistling sound that comes out while breathing out, especially in children. A lack of wheezing and a normal chest examination do not exclude asthma.
- History of any of the following:
  - Cough (worse, particularly at night)
  - Recurrent wheeze
  - Recurrent difficulty in breathing
  - Recurrent chest tightness.
- Symptoms occur or worsen in the presence of:
  - Exercise
  - Viral infection
  - Inhalant allergens (e.g. animals with fur or hair, house dust-mites, mold, pollen)
  - Irritants (tobacco or wood smoke, airborne chemicals)
  - Changes in weather
  - Strong emotional expression (laughing or crying hard)
  - Stress
  - Menstrual cycles.
- Symptoms occur or worsen at night, awakening the patient.

Recommended Methods to Establish the Diagnosis According to Expert Panel Report III

1. Detailed medical history.
2. Physical examination: It may reveal findings that increase the probability of asthma, but the absence of these findings does not rule out asthma because the disease is variable and signs may be absent between episodes. The examination focuses on:
   - Upper respiratory tract (increased nasal secretion, mucosal swelling, and/or nasal polyps);
